Ferritin is an indicator of macrophage activation and it is significantly increased in HLH, often 10 to 100 times higher than normal. Hyperferritinemia is found in essentially all pediatric HLH where it has a relevant diagnostic value (especially in so-JIA HLH); it is also increased in the vast majority of cases of adult-onset HLH,[3,14,15] but its specificity is lower,[4] since high ferritin levels have been reported in adults with variable diseases, such as infections, hematologic neoplasm, autoimmunity, and hepatocellular injury.[99] If both ferritin and sIL-2R are not significantly raised, the diagnosis of HLH should be questioned.[3] However, low percentages of ferritin

glycosylation, indicating a macrophage origin, may be a unique finding of SHLH.[100]

HLH is almost always associated with high blood levels of sIL-2R (sCD25) and sCD163, respectively indicating activation of T cells and macrophages.[14-16] Reduced cytotoxic CD8-positive T cell and NK cell activity is often reported, reflecting either genetic deficiency or the effects of inflammation and immunosuppression.[10,18,101]

Early recognition of HLH is critical, because patients can decompensate rapidly and progress to multiorgan failure and death. The diagnosis of HLH requires awareness, but even when suspected, it is still challenging because there are no clinical, laboratory, or histopathologic findings pathognomonic for the disease. Over time, various criteria for HLH diagnosis have been proposed, some of them reserved for specific clinical conditions.

Diagnostic criteria for children with FHLH were developed in the early 90s (HLH 94)[1] and later updated (HLH 2004).[102] According to HLH 2004 criteria, diagnosis of FHLH requires five of the following eight features: fever; splenomegaly; cytopenias affecting ≥2 of 3 cell lineages and with defined thresholds for hemoglobin, platelets, and neutrophils; hypertriglyceridemia or hypofibrinogenemia; hemophagocytosis; hyperferritinemia; high sIL-2R levels; and low/absent NK cell activity (**Box 52-1**). Otherwise, the diagnosis of FLHL can be made by genetic testing, although this procedure, as well as NK cell activity and sIL-2R assays, are not always immediately available to most institutions.[102] Perforin and CD107a tests by flow cytometry assay are more sensitive and no less specific compared with NK cytotoxicity testing for screening for genetic HLH, and it has been suggested that these be added to current HLH

diagnostic criteria.[103] It is worth mentioning that hemophagocytosis, despite featuring in the name of the disease, has limited diagnostic sensitivity and specificity, because it may not be always present or easily detected in bone marrow biopsies, and it can be observed in patients without HLH.[104-106] Lastly, hyperferritinemia is a sensitive criterion but has low specificity because it can be seen in many other inflammatory and noninflammatory conditions.[99] Although the HLH 2004 criteria are widely used to define and diagnose HLH, including forms other than FHLH, it has been recommended that all criteria, including hemophagocytosis, need not be met for initiating therapy in cases with strong suspicion of HLH.[3,4] Recently, an HLH-probability calculator (H-score) has been developed[107] (**Box 52-2**) showing higher sensitivity compared with HLH-2004 criteria but a lower, still-acceptable specificity.[107-109] The H-score is particularly useful to support the recognition of nonfamilial forms of HLH at initial presentation of the disease but has also been validated in adults with some differences in the cutoff values.[108] In a large cohort of patients with hematologic neoplasms, Zoref-Lorenz et al. showed that the simple combined elevation of soluble CD25 (>3999 U/mL) and ferritin (>1000 ng/mL) accurately identifies HLH, including cases missed by the HLH 2004 criteria, and at the same time is a potent predictor of mortality across diverse hematologic malignancies.[110] Specific scores to identify MAS/HLH associated with so-JIA have also been developed, including the "MS score," found to be particularly useful to distinguish so-JIA with MAS from active so-JIA without MAS, and a score helping to discriminate between FHLH and so-JIA-MAS/HLH.[74,111]

Box 52-1 Updated Diagnostic Hemophagocytic Lymphohistiocytosis—2004 Criteria

Presence of either:

(A) Molecular diagnosis consistent with HLH

or

(B) Presence of at least five of the eight following criteria:

1. Fever ≥38.5° C
2. Splenomegaly
3. Cytopenia affecting ≥2 of 3 lineages:
   - Hemoglobin <9 g/dL (infants <4 weeks: <10 g/dL)
   - Platelets $<100 \times 10^3$/mcL
   - Neutrophils $<1 \times 10^3$/mcL
4. Hypertriglyceridemia or hypofibrinogenemia
   - Fasting triglycerides ≥265 mg/dL
   - Fibrinogen ≤1.5 g/L
5. Hemophagocytosis in bone marrow or spleen or lymph nodes or liver
6. Low or absent natural killer cell activity
7. Ferritin ≥500 mcg/L
8. Soluble CD25 ≥2400 U/mL

Data from Griffin G, Shenoi S, Hughes GC, Hemophagocytic lymphohistiocytosis: an update on pathogenesis, diagnosis, and therapy. *Best Pract Res Clin Rheumatol*, 2020. 34(4): p. 101515. Henter JI., et al., HLH-2004: Diagnostic and therapeutic

guidelines for hemophagocytic lymphohistiocytosis. *Pediatr Blood Cancer*, 2007. 48(2): pp. 124-131.

Morphology

The histologic counterpart of the mutual activation of lymphocytes and macrophages occurring in HLH is represented by prominent tissue accumulation of these cells, with macrophages exhibiting a variable degree of hemophagocytosis, consisting of the cytoplasmic engulfment of nucleated and nonnucleated red blood cells, neutrophils, lymphocytes, or their remains (**Fig. 52-1**).

Hemophagocytosis can be present in virtually all organs, but it typically occurs in the bone marrow, spleen, lymph nodes, liver, or body fluids.[9] It has also been found in the CNS,[112] skin, lungs, and rarely in the subcutaneous tissue.[113] The bone marrow is the tissue most commonly used for the identification of hemophagocytosis and aspirate morphology is often more effective than biopsies (84% versus 64%),[10] where the hemophagocytic cells may be very difficult to discern. Notably, in bone marrow biopsies the occurrence of abnormal clusters of red blood cells with pomegranate seed–like features should prompt to check for the presence of macrophages phagocytosing nucleated cells[114]; moreover, immunohistochemistry (IHC) stains for macrophage markers (such as CD68, CD163, or CD11c) significantly helps in their identification (**Fig. 52-2**).[62,105,115]

Box 52-2 Diagnostic H-Score Criteria

H-Scores higher than 169 are 93% sensitive and 86% specific for HLH. The H-scores can be calculated using the online H-Score

calculator (**http://saintantoine.aphp.fr/score/**).*AST,* Aspartate aminotransferase; *WBC,* white blood cell.

Known Underlying Immunosuppression:

- No = 0
- HIV-positive or receiving long-term immunosuppressive therapy (i.e., glucocorticoids, cyclosporine, azathioprine)= +18

Temperature (°C):

- <38.4 = 0
- 38.4–39.4 = +33
- >39.4 = +49

Organomegaly:

- No = 0
- Hepatomegaly or splenomegaly = +23
- Hepatomegaly and splenomegaly = +38

Number of Cytopenias (Defined as Hemoglobin ≤9.2 g/dL (≤5.71 mmol/L) or WBC ≤5000/mm^3 or Platelets ≤110,000/mm^3):

- 1 lineage = 0
- 2 lineage = +24
- 3 lineage = +34

Ferritin, ng/mL (or mcg/L):

- <2000 = 0
- 2000–6000 = +35
- 6000 = +50

Triglyceride, mmol/L

- <1.5 = 0
- 1.5–4 = +44
- >4 = +64

Fibrinogen, g/L:

- >2.5 = 0
- ≤2.5 = +30

AST U/L:

- <30 = 0
- ≥30 = +19

Hemophagocytosis Features on Bone Marrow Aspirate:

- No = 0
- Yes = +35

Data from Fardet L., et al., Development and validation of the HScore, a score for the diagnosis of reactive hemophagocytic syndrome. *Arthritis Rheumatol*, 2014. 66(9): pp. 2613-2620. Debaugnies F., et al., Performances of the H-Score for Diagnosis of

Hemophagocytic Lymphohistiocytosis in Adult and Pediatric Patients. *Am J Clin Pathol*, 2016. 145(6): pp. 862-870.

The histiocytes have a mature appearance, and are commonly large with abundant cytoplasm, but occasionally can be small. They may occur in clusters or dispersed among the normal bone marrow cells, which tend to become progressively hypoplastic and, in severe cases, are completely replaced by the histiocytic infiltration.

In suspected SHLH, biopsies of the bone marrow, lymph nodes, and also skin and liver have been found to be useful to identify HLH triggers, mostly represented by hematologic neoplasms and infections (**Fig. 52-3**).[113,116] Liver involvement is characterized by Kupffer cell hyperplasia, and hemophagocytosis is generally detected in the sinusoids (**Fig. 52-4A**). Lymphocytes and histiocytes, with enrichment of CD3, CD8, and granzyme B–positive lymphocytes, involve the portal spaces, resembling chronic persistent hepatitis.[113,117] Massive liver involvement can lead to progressively altered liver function and acute liver failure.[118] More rarely, liver changes resemble leukemia, giant cell hepatitis, and storage diseases.[117] Examination of lymph nodes and spleen may show profound generalized lymphoid depletion with sinusoidal infiltration by hemophagocytic histiocytes (**Fig. 52-4B**), and in some patients a massive infiltration of histiocytes involves virtually the entire organ.[112] Rashes may correlate with lymphocyte infiltration on skin biopsy, where hemophagocytosis may also be found. In cases with CNS involvement, cerebrospinal fluid analysis shows pleocytosis, sometimes including hemophagocytic cells, and hyperproteinemia. Brain biopsy reveals T-cell and histiocytic infiltrates.[3,4]

As mentioned before, hemophagocytosis, despite featuring in the name of the disease, has limited diagnostic sensitivity and specificity, and because it is often cyclical, it may not be clearly apparent early in the disease process.[104] Moreover, the presence of rare histiocytes showing erythrophagocytosis in the bone marrow is a common finding, and increased hemophagocytosis may be encountered in patients without HLH, in the setting of sepsis, blood transfusions, hematopoietic transplantation, chemotherapy, and myelodysplastic syndromes (MDS).[104-106,119] Thus, there is no consensus on the differentiation of pathologic hemophagocytosis from the physiologic process,[104,106] and quantification of hemophagocytic cells in aspirates or in core biopsies does not correlate well with disease probability, even when present in high numbers.[105]

Notably, hemophagocytosis is the only HLH-2004 diagnostic criterion without a defined threshold value and no accepted diagnostic threshold or guidelines have been established. Gars et al.[120] studied the bone marrow aspirates of 78 patients presenting with clinical features suspicious for HLH, 40 with and 38 without HLH, and demonstrated that nonnucleated erythrophagocytosis alone is a non-specific finding, while hemophagocytosis of nucleated hematopoietic cells with quantitative thresholds for each of the lineages of ingested cell (at least one granulocyte, or four nucleated erythrocytes, or six cells from any four lineages among red blood cells, nucleated red blood cells, neutrophils, and lymphocytes in 1000 nucleated cells, or multiple nucleated cells in at least one hemophagocyte), revealed a strong association with HLH.

In anticipation of additional prospective studies for the validation of these data, at the present time it is reasonable to consider

hemophagocytosis as neither necessary nor sufficient for diagnosing HLH. Its finding should not be overinterpreted in the absence of other clinical or biological features suggestive of HLH, and its absence should also not delay or even prevent the initiation of therapy whenever HLH is highly suspected.[3,4]

Immunophenotype

The hemophagocytic macrophages express various histiocytic markers and in some cases also show variable, generally weak expression of S100, in contrast to the histiocytes of Rosai-Dorfman disease (RDD), which are strongly positive.[121,122] A CD14-dim, CD16-bright monocytic population has been described in one case: a phenotype associated with macrophages that secrete interleukin-1β, interleukin-6, and TNF-α.[123] Upregulation of CD163 (a receptor for hemoglobin-haptoglobin complexes) on monocyte-macrophages facilitates hemophagocytosis. The plasma levels of soluble CD163 in HLH are considerably higher than those found in infections, autoimmune diseases, and cancer.[124,125]

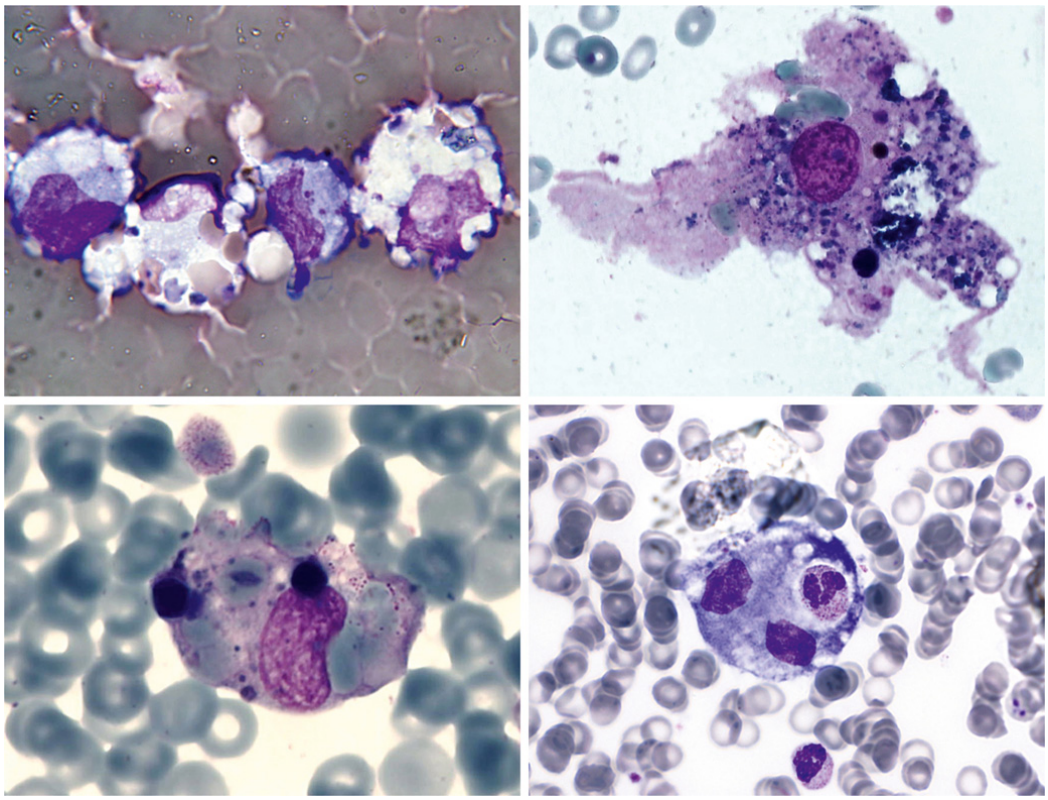

FIGURE 52-1 Hemophagocytic lymphohistiocytosis. Examples of bone marrow smears showing macrophages with phagocytosis of red blood cells, nucleated red cells, neutrophils, and cell debris. The upper left image is from a case of primary (familial) hemophagocytic lymphohistiocytosis (FHLH); the remaining are from secondary HLH (SHLH), all associated with lymphoma.

In individuals with perforin gene mutations, perforin intracellular staining by flow cytometry or IHC is significantly lower or totally absent in cytotoxic lymphocytes (NK cells, CD8-positive T cells, CD56-positive T cells), while it is normal in other forms of FHLH and EBV-associated HLH.[126,127] Downregulation of CD5 along with

reduced CD7 expression by flow cytometry in circulating and bone marrow CD8-positive T cells has been described in some patients with FHLH and EBV-HLH,[128-130] and it may be used to distinguish EBV-positive from EBV-negative HLH.[131] Activated CD8-positive T cells in young patients with either FHLH or SHLH show high CD38 and HLA-DR expression and the presence of more than 7% of CD38-positive/HLA-DR-positive cells among CD8-positive T cells distinguishes HLH from early sepsis or healthy controls significantly.[132] To protect the cytotoxic cell from preformed perforin and granzymes, the granules are lined with LAMP-1 (CD107a) protein, which can be measured by flow cytometry on the cell surface after degranulation. Decreased expression of CD107a has been reported to predict defects in genetic HLH, providing a useful screening tool.[103,133]

Clinical Course and Prognosis

HLH is typically lethal without intervention, and the initial goal consists of suppressing the hyperinflammatory process and treating the underlying trigger. Before the introduction of standardized therapeutic regimens, most patients with FHLH had a rapid downhill clinical course, and death within the first year of life was common. Clinical deterioration is characterized by hemorrhage, sepsis, and neurologic impairment. With the introduction of HLH-94[134] and HLH-2004[102] treatment protocols, the survival of children with FHLH markedly improved, with a 5-year survival rate of up to 54%.[95,135] However, FHLH survivors can develop long-term side effects, such as cognitive and growth delay, hearing impairment, and obstructive lung disease.[95]

In adults, the length and dosing of the HLH-94 treatment protocol has been adapted to the individual patient, taking into consideration the conditions acting as triggers and the associated morbidities.[73] Nevertheless, in adults, HLH prognosis remains poor, especially in elderly patients with comorbidities. Malignancy, particularly lymphoma, has been found to represent an adverse prognostic factor in several studies, with worse outcome in T-cell lymphomas compared with B-cell lymphomas.[136,137] A retrospective review across three tertiary care centers identified 68 adults with HLH, with an average age of 53 years (range 18–77) and a predominance of males (63%). Underlying diseases included malignancy (33, 49%), infection (22, 33%), autoimmune disease (19, 28%) and idiopathic HLH (15, 22%). Forty-six (69%) patients died after a median follow-up of 32.2 months, and the median overall survival was 4 months. The presence of malignancy was a negative prognostic factor.[136] In a series of 162 adult patients with HLH, half of whom had an underlying malignancy, 31% were alive at a median follow-up of 32 months, with an overall mortality rate of 42%, and 20.4% mortality at 30 days. Negative prognostic factors were age, thrombocytopenia, underlying lymphoma, and no etoposide in the management.[13,138]

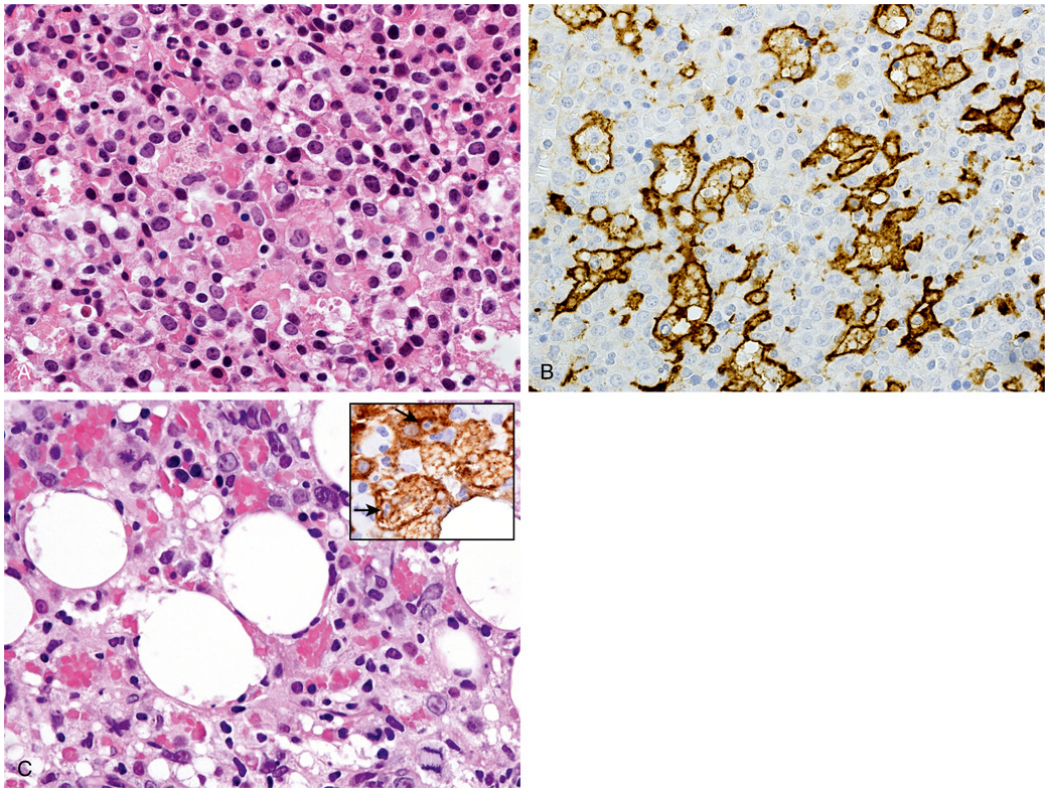

FIGURE 52-2 Hemophagocytic lymphohistiocytosis. Bone marrow biopsy in a patient with acute myeloid leukemia who developed hemophagocytic lymphohistiocytosis (HLH), where hemophagocytosis can be difficult to recognize in hematoxylin-eosin (H&E) stained sections **(A)**, but it is easily revealed by immunostain for CD163 **(B)**. **C,** Bone marrow biopsy in a patient with lymphoma who developed HLH. Note the pomegranate seed appearance of red blood cells engulfed in the cytoplasm of macrophages, which also contain nucleated cells, as best highlighted on the CD163 stained section *(inset, arrows)*.

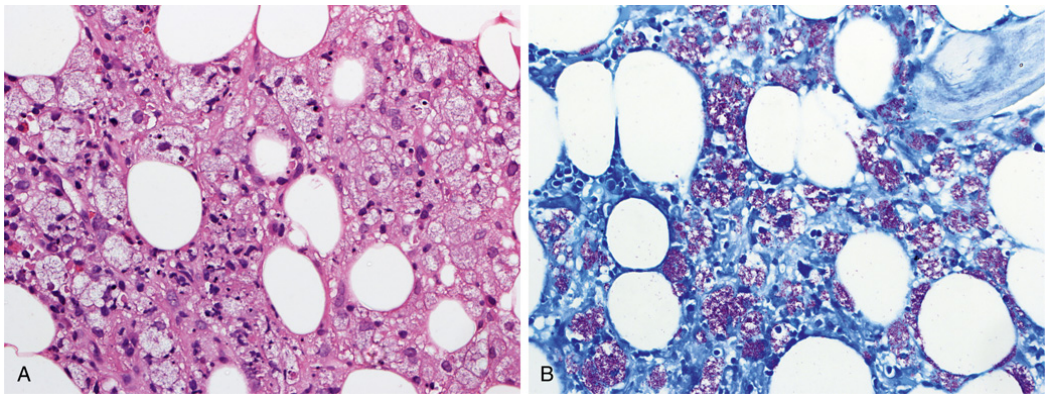

FIGURE 52-3 Hemophagocytic lymphohistiocytosis. Bone marrow biopsy in an immunosuppressed patient who developed hemophagocytic lymphohistiocytosis (HLH) syndrome secondary to disseminated mycobacteriosis: diffuse infiltration of large macrophages engulfing cells and nuclear debris in their cytoplasm **(A)**, which contains countless bacilli positive for Ziehl-Neelsen stain **(B)**.

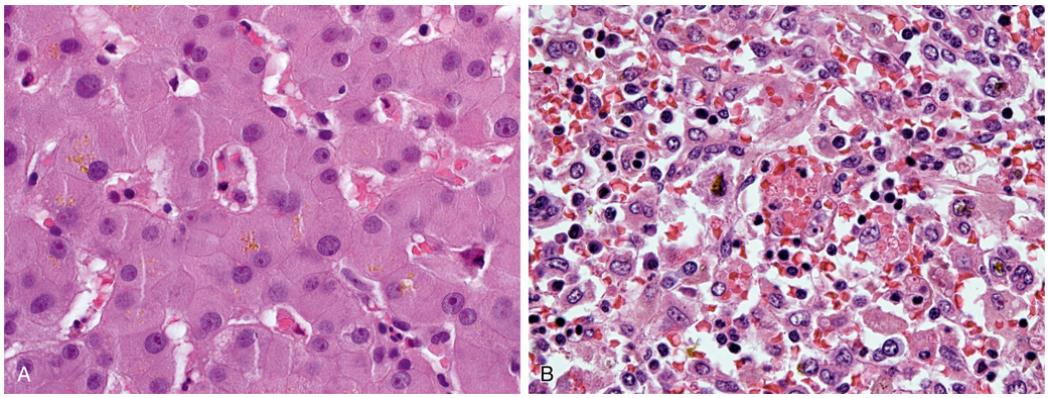

FIGURE 52-4 Hemophagocytic lymphohistiocytosis. Hemophagocytosis, including nucleated forms, is evident in the liver sinusoids of a patient with primary (familial) hemophagocytic syndrome **(A)** and in the spleen sinuses **(B)** from a patient with secondary hemophagocytic lymphohistiocytosis (HLH).

In a retrospective study of 120 adults with secondary nonmalignancy-associated HLH, HLH triggered by EBV had a worse 5-year overall survival (25.1%) compared with HLH occurring in autoimmune diseases (82.4%), non-EBV infections (78.7%), or of unknown origin (55.5%). Other factors associated with poor prognosis included age >45 years, hyperferritinemia, thrombocytopenia, and especially lack of response after 8 weeks of treatment.[139] In another large retrospective study including 260 adult patients, most (64%) with immunosuppression and with different HLH-associated triggers, the overall mortality rate was 57%, and it was unrelated to HLH etiology or the type of treatment, while factors associated with worse prognosis included age, bone marrow aspirate hemophagocytosis, organ failure at admission, and worsening during ICU hospitalization.[140]

Despite the development of standardized treatment protocols, the mortality rate of HLH is still high and research is underway in order to understand as a whole how to improve the diagnosis, better understand HLH pathogenetic mechanisms, and identify treatment strategies and new drugs that can improve the survival. The HLH-94 protocol remains the most commonly used treatment[141] and includes dexamethasone and etoposide, the latter having specific activity against activated T cells.[142] Etoposide can be avoided in patients with mild disease that may respond to corticosteroids alone. An alternative approach includes corticosteroids and antithymocyte globulin (ATG), a polyclonal antibody depleting human T cells, or etoposide and ATG, which has led to complete responses in 50% to 75% of patients.[143,144] HLH-specific treatment may be postponed in patients with HLH caused by infections such as visceral leishmaniasis; histoplasmosis; atypical *Mycobacterium*, *Ehrlichia, Bartonella*, and *Brucella* species; and disseminated adenovirus or herpes simplex infections that can be controlled by antimicrobial therapy alone.[3,113] B-cell depletion treatments such as rituximab should be considered for EBV-associated HLH,[145] while HLH associated with malignancy may improve with oncologic-oriented treatments. Patients with MAS associated with autoimmune or autoinflammatory diseases are primarily treated with the IL1 inhibitor anakinra, high-dose corticosteroids, and cyclosporine, while etoposide is delivered only in cases where inflammation is insufficiently controlled by classical therapies.[101,146,147]

Allogeneic hematopoietic stem cell transplantation upon salvage treatment with full-intensity or reduced-intensity myeloablative protocols[113,148] is generally reserved for patients with severe genetic

HLH disorders, patients with high-risk hematologic malignancy as consolidation treatment, and in refractory or relapsing HLH. Unrelated umbilical cord blood cells have been used successfully as an alternative to allo-HSCT.[149] Novel biological treatments have also been used to control HLH. The monoclonal antibody emapalumab targeting IFNγ has shown significant efficacy for refractory, recurrent, or progressive HLH, with responses in 63% of previously treated patients.[150]

Other approaches aimed at targeting specific immune cells, immune activation pathways, or cytokines include alemtuzumab, a monoclonal antibody against CD52[151]; the Janus kinase (JAK) inhibitor ruxolitinib, which blocks multiple cytokine signaling pathways[152,153]; anakinra, an IL1R antagonist effective in SHLH[154]; and monoclonal antibodies against IL-1, IL-6, and TNF-α, which have shown encouraging results in the treatment of acquired HLH[14] but could possibly be used in the management of FHLH as well, since these cytokines are also elevated in FHLH. The human recombinant IL18 binding protein tadekinig-α may be effective in pediatric patients with NLRC4-MAS and XIAP deficiency.[113,155] On the evidence of encouraging results in murine models, gene therapy targeting the genes involved in XLP1, FHL2, and FHL3 deficiency could open the way for future trials to evaluate the effectiveness of gene therapy as treatment of these forms of HLH.[113] **Table 52-2** lists a number of features distinguishing FHLH and SHLH.

Differential Diagnosis

The diagnosis of HLH is a complex process that must be carried out rapidly, given the lethality of the disease, excluding mimicking

conditions whose pathogenesis differs from that of authentic HLH, thus requiring alternative therapies.

A typical example is represented by sepsis, which significantly overlaps with many clinical features of HLH and can show hemophagocytosis, low NK-cell activity, and high sCD25.[156] Treatment of sepsis significantly differs from that of HLH, and in particular immunosuppression can be harmful in a patient with sepsis.[157] However, when patients with sepsis do not respond to antimicrobials and supportive measures, HLH should be considered and prompt the evaluation for HLH using the HLH-2004 diagnostic criteria.[73],[113]

As HLH may be associated with an underlying lymphoma or leukemia, especially in adults, a search for a concurrent neoplasm should be conducted. Notably, in biopsy samples, the presence of a dense histiocytic reaction may obscure the recognition of the lymphoma.[158] There is evidence suggesting that a high sCD25 to ferritin ratio may point toward a lymphoma as an underlying cause for HLH rather than other secondary causes.[69]

LCH involving the bone marrow or visceral organs and multicentric Castleman disease, especially the TAFRO variant (thrombocytopenia, anasarca, myelofibrosis, renal dysfunction, and organomegaly) may closely resemble HLH. The treatment primarily addressing the underlying condition with or without additional corticosteroids can be effective in managing both of these diseases,[3] although disseminated LCH and TAFRO can, per se, be associated with a dismal prognosis.

Storage diseases in infants, such as Wolman disease (infantile lysosomal acid lipase deficiency) and GD, may present with extreme

organomegaly or pancytopenia simulating HLH, even fulfilling the HLH-2004 criteria.[3,113] In most cases, however, these disorders develop features of HLH not caused by immune hyperactivation.[3] A correct diagnosis is thus important because an HLH-oriented treatment is not indicated in both Wolman disease and GD. In contrast, patients with lysinuric protein intolerance and other metabolic disorders have been reported to develop authentic HLH,[3] with notable inflammatory features which may benefit from immune suppression.[159]

DIHS, also known as DRESS (drug reaction with eosinophilia and systemic symptoms), may present as HLH, with fever, liver function test abnormalities, and, rarely, hemophagocytosis, but generally lacks extremely high ferritin or cytopenias and shows skin rash and eosinophilia with temporal relationship with a drug, thus requiring withdrawal of the triggering drug and eventually corticosteroids.[160]

Certain uncommon clinical conditions can simulate HLH with restricted organ involvement, such as isolated CNS or liver HLH occurring in newborns. Isolated CNS HLH must be differentiated from viral encephalitis, autoimmune disseminated encephalomyelitis, CNS vasculitis, multiple sclerosis, Rasmussen encephalitis, febrile infection-related epilepsy syndrome (FIRES), and acute necrotizing encephalopathy, or interferonopathies.[3] Differential criteria are based on distinctive localization of the disease and imaging (e.g., single hemisphere in Rasmussen encephalitis, symmetric thalamic necrosis in acute necrotizing encephalopathy without marked matter changes, cerebral calcifications in interferonopathies),[3] while FIRES in some cases may really represent HLH.[161]

In newborns presenting with fulminant liver failure, HLH should be distinguished from gestational alloimmune liver disease, also known as neonatal hemochromatosis, associated with extrahepatic siderosis.[162] These patients can present with hyperferritinemia and coagulopathy, while hemophagocytosis and other signs of inflammation are absent.[163]

Increased histiocytes in the bone marrow may be associated with a chronic myeloproliferative disorder or MDS and may not represent HLH. Similarly, reactive lymph nodes with prominent sinus histiocytosis may occasionally exhibit hemophagocytosis. In the absence of the clinical and laboratory features of HLH, this diagnosis should not be proposed on the basis of biopsy findings. Hemophagocytosis can occur in histiocytic sarcoma (HS), but the presence of cell atypia and mitoses easily permit identification of the neoplastic nature of the histiocytes.[164,165]

Table 52-2

Features Distinguish Primary and Secondary Hemophagocytic Lymphohistiocytosis

Familial (Primary) HLH	Secondary HLH
Mendelian inherited conditions resulting in defects of immune regulation leading to hyperimmune states	Acquired conditions, except for rare cases in which an inherited condition is unknown; pathogenetic mechanisms causing the hyperimmune status poorly known
Familial involvement (autosomal recessive)	Not familial in most cases
Presentation in infancy	Presentation mostly in older individuals, except cases associated with autoimmunity
Usually not associated with immunodeficiency	Often associated with immunodeficiency
Onset may be triggered by a viral infection	Onset may be triggered by any infectious agent, malignant neoplasms, and allogenic HSCT

Familial (Primary) HLH	Secondary HLH
Not associated with autoimmunity	Can be associated with autoimmunity
Progressive disease, curable in about 50% of cases	Possible remission if the underlying cause can be eliminated; high mortality in cases associated with malignant neoplasms, especially lymphoma
Treatment mainly oriented toward hyperimmune state control	Treatment mainly oriented to elimination or control of the trigger
Perforin absent and mutations in perforin and other genes (30%)	Perforin expression and gene normal
Normal NK-cell numbers; absent NK-cell function	Normal or reduced NK-cell numbers and equivalent NK-cell function

HLH, Hemophagocytic lymphohistiocytosis; *HSCT,* hematopoietic stem cell transplantation; *NK,* natural killer.

In RDD, nucleated cells are typically engulfed by macrophages, while phagocytosis of red blood cells is uncommon; in addition, numerous plasma cells are often present and the macrophages strongly express S100.[166] Moreover, RDD very rarely involves the bone marrow and its clinical presentation is generally indolent. In

contrast, a severe clinical onset classically occurs in newborns with ALK-positive histiocytosis, a rare disease often involving the bone marrow and sometimes associated with prominent hemophagocytosis.[167]

Extensive hemophagocytosis in the subcutaneous fat tissue is found in cytophagic histiocytic panniculitis, a rare disease associated with nonmalignant conditions, but more often representing the natural disease progression of subcutaneous panniculitis-like T-cell lymphoma.[168,169]

These patients rarely have the severe multiorgan involvement seen in HLH, but some cases evolve in HLH.[168,170,171]

Gaucher Disease

Definition

GD is the most common lysosomal storage disorder and it is inherited as an autosomal recessive trait. It is characterized by lipid storage and accumulation of glycosphingolipids in mononuclear phagocytes. There are three clinical subtypes of GD based on age of onset, disease progression rate, and absence or presence of early neurologic manifestations.[172]

Etiology

GD results from a deficiency in the lysosomal enzyme acid β-glucocerebrosidase, encoded by *GBA* on chromosome 1q21,[173,174] leading to the accumulation of the glycosphingolipids glucosylceramide and glucosylsphingosine in mononuclear phagocytes, primarily macrophages.[175] To date, more than 350 mutations have been reported involving the defective human gene

GBA, the most common of which are p.N370S, p.L444P, and IVS2+1.[176,177] p.N370S and p.L444P account for the majority of mutant alleles in Ashkenazi Jews.[178,179] Type 1 disease is the most common lysosomal storage disorder and has a high incidence in this population.[180] Types 2 and 3 are pan-ethnic, although a variant of type 3 (Norrbottnian type) is reportedly more prevalent in Sweden.[181] A few patients have overlapping presentations that cannot be readily classified as a specific type.[177]

The accumulation of glucocerebrosides causes the release of various cytokines and lysosomal proteins from the activated macrophages, resulting in different presentations of the disease.[182] However, recent data indicate that the pathophysiology of GD is rather complex and may result from interconnection among different biological mechanisms, including oxidative stress, calcium dysregulation, mitochondrial dysfunction, autophagy defects, accumulation of α-synuclein aggregates, altered secretion and function of extracellular vesicles, and immunologic hyperactivity.[172]

Clinical Features

Type 1 GD is the most common variant. Although it is also referred to as “adult type,” it may present clinically at any time between infancy and late adulthood, and it is diagnosed before the age of 20 in more than 50% of cases.[172] It has a wide range of severity, involving predominantly peripheral organs, such as the liver, spleen, skeletal muscle, and bone marrow, without neurologic involvement. Patients show hepatosplenomegaly, pancytopenia, osteolytic bone lesions, degenerative arthritis, and elevated risk of multiple myeloma.[175] Although GD type 1 is categorized as “nonneuropathic,” middle-aged

or elderly patients may develop peripheral neuropathy and symptomatic Lewy body–associated parkinsonism.[172]

Types 2 and 3 are typically neuropathic. Type 2 is acute and rapidly fatal within the first few years of life, whereas type 3 has a later onset and a chronic, progressive course, and it is more clinically heterogeneous than type 2 GD.[172,182] In type 2 GD, patients show limited psychomotor development; bulbar signs, including stridor and swallowing difficulty; stiffened opisthotonic posture; spasticity and trismus; and epilepsy.[175] In type 3 GD, the presenting symptoms include oculomotor apraxia, abnormal horizontal saccadic eye movements, and myoclonic or generalized epilepsy. Some individuals have an aggressive neurodegenerative disease and low life expectancy (6–20 years), while others may have negligible and nonprogressive neurologic symptoms and normal cognitive functions, and with the support of treatment, good quality of life until late middle age.[172,183] A perinatal lethal form of GD is the most severe variant and its complications can begin before birth or in early infancy; it is characterized by hepatosplenomegaly, pancytopenia, skin abnormalities, and nonimmune hydrops fetalis.[175]

Although initial studies of patients with GD demonstrated a 14.7-fold increased risk of cancer, especially hematologic malignant neoplasms,[184-186] more recent larger studies show no higher malignancy risk except for a reported 5.9-fold increased incidence of multiple myeloma.[187,188] Enzyme replacement therapy with recombinant enzyme is the current treatment; it is effective in reducing bone pain and hepatosplenomegaly but has a limited effect on neurologic symptoms.[175,188,189]

GD presents with a range of signs and symptoms that can hinder an early diagnosis, leading to significant delays and sometimes irreversible morbidities. Recently, the Gaucher Earlier Diagnosis Consensus (GED-C) Delphi project identified signs and covariables useful for early GD diagnosis and helping to increase the index of suspicion in recognizing patients suitable for diagnostic testing for GD.[190]

Morphology

The accumulated glucocerebrosides in the lysosomes of macrophages fill the cytoplasm, and on electron microscopy the storage material is composed of membrane-bound structures containing hollow tubules measuring 250 to 725 angstroms in diameter.[191] These macrophages, known as Gaucher cells, appear as large cells, 20 to 100 μm in diameter, with a single small nucleus and a cytoplasm showing a compactly striated or fibrillary pattern, with "wrinkled paper" appearance, reflecting the enlarged and deformed lysosomes, which are highlighted by CD68, recognizing lysosome-associated membrane glycoproteins. The cytoplasm of Gaucher cells stains positively with periodic acid–Schiff (PAS) and acid phosphatase techniques,[192] and pale blue to gray with Wright-Giemsa stain (**Fig. 52-5**).[191] Moreover, Gaucher cells show diffuse iron staining, in contrast to normal marrow histiocytes; this is probably secondary to phagocytosed red blood cells. In the bone marrow, these cells may diffusely replace the medullary cavity or form small aggregates and they are more recognizable in bone marrow biopsy than on smears.[191] The presence of histiocytes with diffuse iron uptake in the

bone marrow suggests GD, and an appropriate clinical workup to rule out the disease should be initiated.[193]

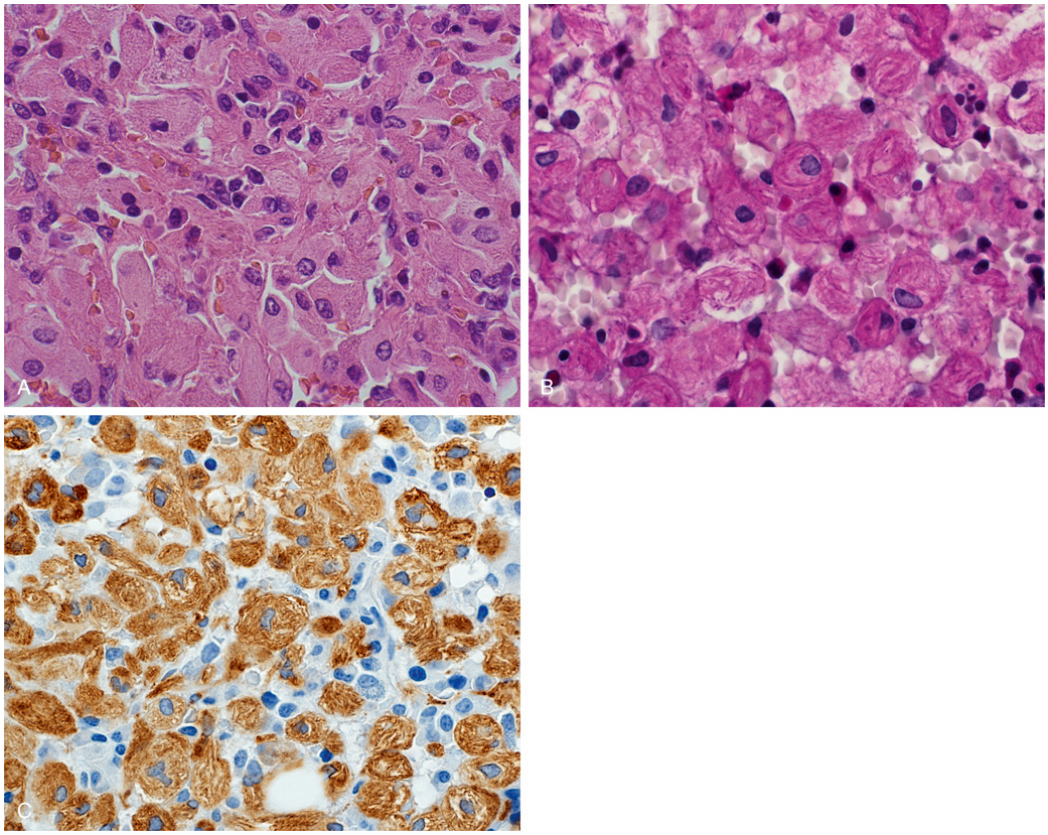

FIGURE 52-5 Gaucher disease. Gaucher cells in a bone marrow biopsy, showing the characteristic wrinkled paper cytoplasm **(A)** and positivity for periodic acid–Schiff (PAS) stain **(B)**. CD68, recognizing lysosome-associated membrane glycoproteins, highlights the peculiar structure of the cytoplasm of Gaucher cells **(C)**.

Although an extensive infiltration of Gaucher cells in bone marrow biopsies strongly suggests GD, enzymatic assays for β-glucocerebrosidase activity in leukocytes and molecular analysis are

the gold standard for GD diagnosis.[194,195] Plasma chitotriosidase levels, which are significantly elevated in GD, can also aid in establishing the diagnosis and can be used to monitor response to therapy as well.[177]

Currently clinical exome sequencing is extensively used in clinical practice[196] and multiplex ligation-dependent probe amplification has shown to be useful in the detection of *GBA* deletions and recombinations.[197,198]

Differential Diagnosis

Other disorders that cause the accumulation of histiocytes in tissues, such as other storage diseases, hemophagocytic syndromes, LCH, and infections are included in the differential diagnosis of GD. The most tricky differential diagnosis is represented by the occurrence of so-called "pseudo-Gaucher cells," which may be seen in various conditions characterized by increased cell turnover, especially in the bone marrow of patients with hematologic neoplasms, particularly chronic myelogenous leukemia.[199] They also occur in multiple myeloma, severe chronic hemolysis, congenital dyserythropoietic anemia, and other conditions.[191] These pseudo-Gaucher cells may have an identical cytologic appearance to true Gaucher cells, but generally are less prominently striated, are weakly PAS positive, and are positive for fat stains such as Sudan black B.[191]

In the spleen, red pulp histiocytosis can be prominent in patients with chronic idiopathic thrombocytopenic purpura, mimicking a storage disease. However, the identification of Gaucher cells with the characteristic cytoplasmic wrinkled paper appearance, in association

with the typical clinical and laboratory findings, establishes a diagnosis of GD.

Niemann-Pick Disease

Definition

NPD is an autosomal recessive lipid storage disorder that is characterized by an accumulation of sphingomyelin and cholesterol in the lysosomes of cells of the macrophage-monocyte system, resulting in the accumulation of foamy histiocytes in the bone marrow, spleen, liver, and lymph nodes. NPD is classified into three main subtypes: NPD types A and B are caused by a congenital deficiency of sphingomyelinase, while NPD type C is pathophysiologically unrelated to types A and B and is caused by a defect in intracellular lipid transport.

Etiology

NPD types A and B are caused by a deficiency in acid sphingomyelinase activity resulting from mutations of the acid sphingomyelinase gene *(SMPD1)*.[200] Three common missense mutations account for more than 90% of the mutant alleles in individuals of Ashkenazi Jewish ancestry in type A, whereas the most frequent mutation in type B is p.R608del.[201-203] Type C NPD is caused by a defect in the intracellular cholesterol transport from the lysosome to the cytosol because of either *NPC1* (intracellular cholesterol transporter 1) or *NPC2* mutations,[202,204] resulting in the overaccumulation of cholesterol and glycosphingolipids in late endosomal/lysosomal compartments. An *NPC1* mutation, mapped to chromosome 18q11, occurs in the majority of patients (95%),[205-207]

whereas mutations in *NPC2,* mapped to chromosome 14q24.3, are rare.[175,206,208-210]

Dementia is a common symptom in patients with NPD type C, and postmortem studies of brains have shown many histopathologic features typically associated with late-onset Alzheimer disease, suggesting that the cell biology of NPD type C involves acceleration of processes typically found in this disease and associated with aging in the general population.[175]

Clinical Features

NPD type A patients present in early infancy with hepatosplenomegaly, failure to thrive, and a rapidly progressive neurologic course; death usually occurs within the first 2 years of life.[203] In contrast, patients with type B disease have a later onset of symptoms, and sometimes the diagnosis is made when they are adult. Patients present in late childhood with hepatosplenomegaly that eventually leads to liver cirrhosis and progressive pulmonary disease. Neurologic symptoms are lacking, the clinical course is more variable, and fatalities can occur in early adulthood.[203] The clinical severity and organ involvement in NPD types A and B are related to the level of residual SMPD1 activity, which is almost undetectable in patients with type A disease, whereas type B patients typically have 10% to 20% of normal activity, which presumably prevents the development of neurologic symptoms.

NPD type C patients exhibit a variable age at diagnosis and are clinically heterogeneous.[207,211] Hepatosplenomegaly is less prominent than in the other NPD types and may be absent. Three type C NPD clinical subtypes have been described, based on the age

at onset of neurologic symptoms: infantile (including early-infantile and late-infantile), juvenile, and adolescent/adult-onset disease forms.[210] *NPC1* mutations are most commonly associated with the juvenile-onset form,[206,207] which typically presents with neonatal jaundice that eventually resolves, followed by an asymptomatic period, and subsequently by progressive neurologic deterioration. The age at onset of neurologic manifestations is an important parameter to assess, as patients with early-onset symptoms tend to have a more morbid clinical course and increased fatality rates.[210]

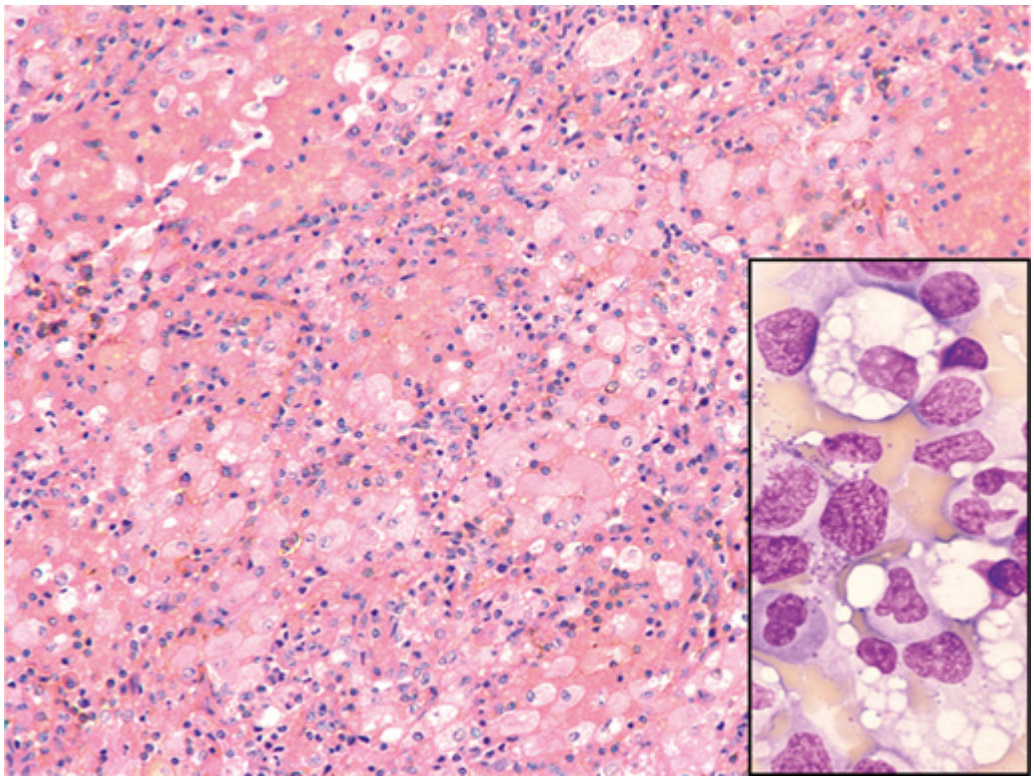

FIGURE 52-6 Niemann-Pick disease. Spleen from a patient with Niemann-Pick disease (NPD) showing aggregates of foam cells. The *inset* shows histiocytes in the bone marrow with distended cytoplasm caused by the presence of vacuoles that are characteristic of foam cells (Niemann-Pick cells). Inset courtesy Dr. Russell Brynes.

Morphology

In blood smears, lymphocytes with numerous sharply defined lipid vacuoles may be observed, while in bone marrow smears and biopsies two types of histiocytes are present: classic Niemann-Pick cells and sea-blue histiocytes.[191] The Niemann-Pick cells are enlarged macrophages with a single, often eccentric nucleus and

abundant cytoplasm that is distended by vacuoles that contain sphingomyelin and cholesterol, resulting in the characteristic foamy cells (**Fig. 52-6**). The cytoplasm may also appear granular or partially vacuolated, and it is sometimes entirely occupied by large vacuoles. The presence of foam cells in the bone marrow space, red pulp sinusoids of the spleen, or intraparenchymal sinusoids of the liver is highly suggestive of NPD, but not pathognomonic. In advanced disease, aggregates of foam cells can replace the architecture of the organ involved. Sea-blue histiocytes are large histiocytes containing in their cytoplasm bright blue cytoplasmic granules of varying size. They may also contain vacuoles, and transitional forms between the foamy cells and sea-blue histiocytes can be observed.[191] In NPD type A, the "foamy" histiocytes predominate,[212] while in NPD types B and C, the sea-blue histiocytes are more often present and may predominate. Classic NPD cells stain with lipid stains such as Sudan black B and oil red O, and are weak or negative with PAS. Sea-blue histiocytes stain blue with May-Grünwald-Giemsa and are variably positive for PAS and Sudan black B.[191] On electron microscopy, the classic NPD cells contain lipid inclusions ranging from 0.5 to 50.0 μm in size, some with a lamellar appearance.

The diagnosis of NPD types A and B is confirmed by demonstration of reduced SMPD1 enzymatic activity in tissue samples, leukocyte extracts, or cultured skin fibroblasts.[200,213] In type C, NPD diagnosis is provided using filipin staining to demonstrate accumulated unesterified cholesterol in cultured fibroblasts or peripheral blood cells, and in positive cases by validation by DNA mutational analysis.[213,214] The measurement in

plasma of 7-ketocholesterol and cholestanetriol have been reported to be useful screening tools, providing important diagnostic support for a disease that, because of its heterogeneous clinical phenotype, is often diagnosed with a delay of many years or even totally missed.[215,216]

Differential Diagnosis

The differential diagnosis of NPD includes any disorder in which histiocytes infiltrate and accumulate in tissues, such as infectious diseases, hemophagocytic syndrome, and other storage disorders. Hyperlipidemias can cause lipid accumulation in the cytoplasm of histiocytes, thus mimicking NPD cells; however, the presence of hepatosplenomegaly and bone marrow infiltration, along with identification of decreased sphingomyelinase activity in leukocytes, confirms the diagnosis of NPD. Sea-blue histiocytes may be present in variable numbers in high cell turnover states in which pseudo-Gaucher cells are also seen,[191] while marked infiltration of sea-blue histiocytes may occur in hyperlipidemic states and in patients receiving total parenteral nutrition containing lipid emulsions.[217] Foamy histiocytes are also found in Erdheim-Chester disease (ECD), but the association with progressive fibrosis and, especially, the markedly different clinical presentation easily allows its distinction from NPD.

Tangier Disease

Definition

Tangier disease (TD) is a rare autosomal recessive disorder characterized by severe deficiency or absence of high-density

lipoprotein (HDL) in the circulation, and tissue accumulation of cholesteryl esters throughout the body, particularly in tissue macrophages.[218,219]

Etiology

TD is caused by pathogenic variants in the *ABCA1* gene, which encodes the ATP-binding cassette transporter A1,[220,221] which facilitates the efflux of cholesterol from cells to emerging HDL particles. Loss-of-function *ABCA1* variants result in reduced ABCA1 synthesis or activity and a diminished cholesterol efflux capacity. In homozygotes, the impaired efflux of free cholesterol from cells and the intracellular accumulation of cholesteryl esters prevent the conversion of lipid-poor apoA-I into preβ-HDL particles, while heterozygotes display an intermediate phenotype with low HDL-cholesterol and about 50% decrease in ABCA1-mediated cholesterol efflux.[218]

Most of the clinical manifestations of TD are largely because of the deposition of sterols in tissues.[220,222] Thrombocytopenia is caused by the sequestration of platelets in the enlarged spleen; in addition, altered platelet morphology and impaired platelet function and defective activation may be caused by reduced ABCA1 expression on platelets.[223]

Clinical Features

The main clinical features of TD include hyperplastic yellow-orange tonsils, hepatosplenomegaly, and peripheral neuropathy. Other complications include premature atherosclerotic coronary artery disease, corneal opacities, skin lesions, mild thrombocytopenia, reticulocytosis, stomatocytosis, or hemolytic anemia. In some

individuals, the disease is clinically silent and only biochemical anomalies are recognizable. Peripheral neuropathies are found in 51% of patients, usually occur after the age of 15 years and consist of relapsing-remitting mononeuropathy or polyneuropathy.[224]

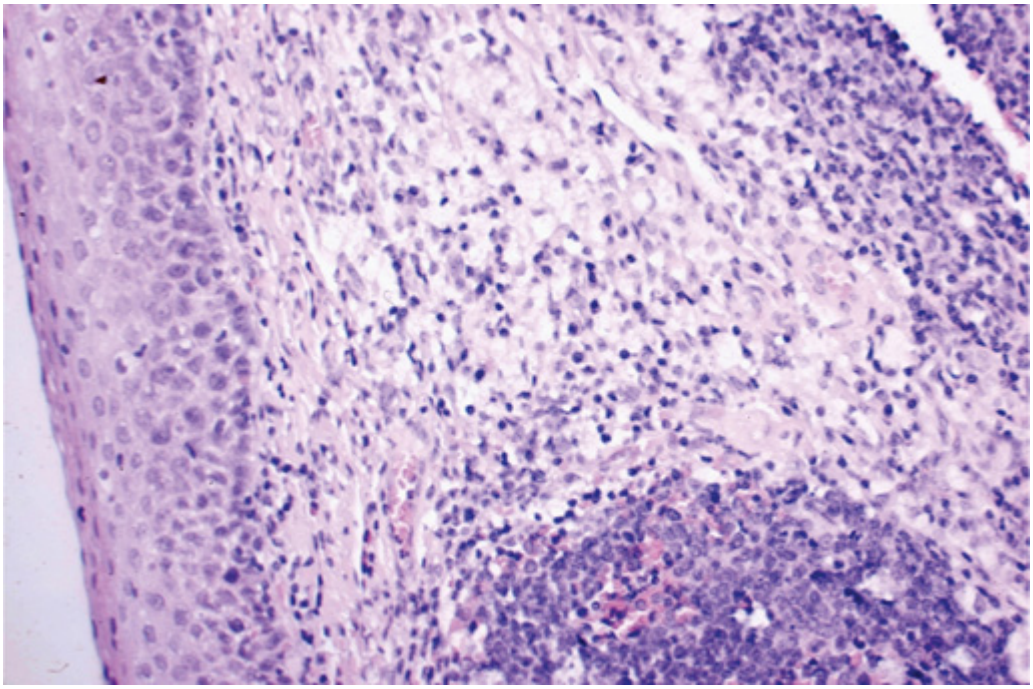

FIGURE 52-7 Tangier disease. Tonsil of a patient with Tangier disease showing accumulation of mature histiocytes in association with reactive lymphoid tissue. Courtesy Dr. Russell Brynes.

Despite patients with TD having very low or absent plasma HDL-cholesterol (<5 mg/dL) and very low or absent plasma apoA-I (<30 mg/dL),[218] 25% to 44% of them develop coronary artery disease,[225,226] perhaps owing to the partial protection offered by the coexistence of decreased low-density lipoprotein.[220] In a study including 185 patients with TD,[226] 25% had cardiovascular disease

(about half of those aged 40–65 years), compared with 11% of age- and sex-matched controls.[226] Notably, premature atherosclerotic coronary artery disease is observed in TD patients but also in heterozygous carriers of *ABCA1* variants.[227] No effective treatment is currently available for this disorder, but glycosphingolipid inhibition represents a potential novel therapy for the neurologic complications.[228]

Morphology

Microscopically, the affected tissues demonstrate a marked accumulation of histiocytes with a large pale microvacuolar cytoplasm, containing lipid droplets and occasionally crystalline material. Lipid droplets are unbounded by membranes and are not present in lysosomes.[229,230] In tonsils and lymph nodes, the foamy histiocytes aggregate in clusters in the parafollicular area. Foamy histiocytes have also been detected in the thymus, skin, Schwann cells in peripheral nerves, and colonic and rectal mucosa, while they are scanty in the bone marrow and spleen.[229-231] Tissue accumulation of lipid-laden macrophages provides a clue to the diagnosis of TD but is not pathognomonic (**Fig. 52-7**). The clinical symptoms and the extremely low levels of HDL usually establishes the diagnosis, which is confirmed by detecting an *ABCA1* mutation.

Histiocytic and Dendritic Cell Neoplasms

Introduction

Histiocytic/dendritic cell (H/DC) neoplasms, often collectively referred to as *histiocytoses*, are derived from the macrophages, dendritic cells, and monocytes of the mononuclear phagocyte system. The term *histiocyte* is a morphologic term, variably referring to a tissue-resident macrophage[2] or to the group of immune cells that includes macrophages and dendritic cells.[232] Conventional (myeloid) dendritic cells and plasmacytoid dendritic cells are derived from bone marrow precursors[233] and Langerhans cells and tissue-resident macrophages, including microglia, are now thought to be long-lasting and self-renewing populations derived from fetal yolk sac erythro-myeloid progenitors.[234,235] However, it has been shown in mice models that bone marrow–derived myeloid precursors, including monocytes, can replenish these cell populations in an inflammatory context by differentiating into macrophages or Langerhans cells at sites of inflammation.[233,236] Thus, there is great heterogeneity and plasticity among the cells of the mononuclear phagocyte system, as well as complex cellular origins. Although follicular dendritic cell sarcomas (FDCSs) have been traditionally grouped under the category of *H/DC neoplasms*, unlike most other neoplasms in this category whose origins appear to be from bone marrow–derived precursor cells, these tumors are derived from follicular dendritic cells (FDCs) that are of mesenchymal origin.[237] FDCs have been intensively studied in lymph nodes, where they participate as antigen-presenting cells in the germinal center

reaction,[238] but FDCS is not restricted to lymph nodes and may occur in extranodal sites as well.[239]

There are currently three systems used to classify neoplasms of histiocytic and dendritic cell lineages: the International Consensus Classification (ICC)[240] (**Box 52-3**); the World Health Organization (WHO) classification[241] (**Box 52-4**), which is currently in its 5th edition; and the 2016 revised classification of histiocytoses and neoplasms of the macrophage-dendritic cell lineages of the Histiocyte Society[2] (**Box 52-5**). The more recent ICC and WHO classifications include ALK-positive histiocytosis as a distinct disease type. Other changes in the WHO 5th edition classification are the inclusion of RDD and clonal plasmacytoid dendritic cell diseases in the *H/DC neoplasia* category and the moving of the mesenchymal stromal cell-derived FDCS and fibroblastic reticular cell tumor to a separate category. The revised classification from the histiocyte society divides the histiocytoses into five groups based on clinical, radiographic, pathologic, phenotypic, genetic, or molecular features while also incorporating hemophagocytic syndromes.[2]

Immunohistochemical and Molecular Evaluation of Histiocytic Disorders

IHC studies are essential in the diagnosis of histiocytic neoplasia and play a key role in distinguishing between the various subtypes. A basic IHC panel at diagnosis should include CD163, CD68, S100, CD1a, langerin (CD207), factor XIIIa, ALK, and cyclin D1. IHCs with *BRAF* p.V600E-specific antibody (VE1) is also recommended in suspected LCH and ECD, but negative or equivocal IHC for this antibody does not exclude mutated *BRAF* p.V600E[242] (**Table 52-3**).

Molecular evaluation by next-generating sequencing (NGS) and fusion testing has become increasingly important. The detection of activating alterations in RAS/RAF/MAPK/ERK and PI3K/AKT pathway genes not only aids in the diagnosis of histiocytic neoplasia, but also identifies potential targets for systemic therapy. NGS should assess for targetable somatic variants in common MAPK pathway genes such as *BRAF, MAP2K1, KRAS, NRAS, PIK3CA, ARAF, RAF1, MAP2K2, MAP3K1,* and *CSF1R*. Fusion testing should include *BRAF, ALK,* and *NTRK1* rearrangements.[242]

Langerhans Cell Histiocytosis

Definition

Langerhans cell histiocytosis (LCH) is neoplastic H/DC disorder characterized by tissue infiltration by S100-positive/CD1a-positive/langerin (CD207)-positive cells and driven by activation of the MAPK pathway. *BRAF* p.V600E mutations are present in more than half of cases.[243]

Synonyms and Related Terms

Langerhans cell histiocytosis (ICC); Langerhans cell histiocytosis (WHO 5th ed.); Langerhans cell histiocytosis (WHO Revised 4th ed.); Langerhans cell histiocytosis (Revised Classification of the Histiocyte Society, 2016).

Background

Historical aspects of LCH have been detailed in a number of reviews.[244-246] One of the earliest descriptions in modern times has been attributed to Dr. Thomas Smith in 1865 who described a child with impetigo and three large holes in the calvarium, which he surmised to be congenital lesions.[247] A few decades later, a number of apparently separate diseases with characteristic clinical features emerged. In 1893, Dr. Alfred Hand reported a 3-year-old boy with exophthalmos who presented with polydipsia and polyuria and was found to have a skull lesion at autopsy.[248] Similar patients were also described in 1905 by Dr. Thomas W. Kay,[249] in 1915 by Dr. Artur Schüller,[250] and in 1920 by Dr. Henry Christian[251]; this co-occurrence of exophthalmos, diabetes insipidus, and bone lesions became known as Hand-Schüller-Christian disease. Letterer-Siwe

disease, first named in 1936,[252] described a clinical syndrome of hepatosplenomegaly, lymphadenopathy, bone lesions, anemia, purpura, and hyperplasia of nonlipoid-storing macrophages in various organs.[253,254] Isolated bone lesions with similar histologic features to Hand-Schüller-Christian disease were also observed,[255,256] termed *eosinophilic granuloma of the bone* by Jaffe and Lichtenstein.[257] By the early 1940s, overlap between these different disorders was noted, with eventual unification under the name *histiocytosis X*.[258] In 1973, Dr. Christian Nezelof observed similarities between the Langerhans cell and the cells of histiocytosis X, including the common presence of Birbeck granules on ultrastructural examination.[259] The term *Langerhans cell histiocytosis* as a name for the disorder followed,[260] and LCH was integrated into the recommended classification of histiocytosis in children from the Histiocyte Society, published in 1987.[261] Currently, LCH is categorized within the L (Langerhans) group of disorders in the 2016 revised classification of histiocytoses and neoplasms of the macrophage-dendritic cell lineages from the Histiocyte Society.[2]

(monogenic inherited conditions leading to HLH)
Secondary HLH (non-Mendelian HLH)
HLH of unknown/uncertain origin

Epidemiology

LCH is predominantly a disease of children, with an incidence in the literature ranging from 2 to 9 per million children per year.[262,263] In a recent analysis, most cases reported over a 6-year period in the United States were in those under the age of five,[264] decreasing with age. There is a male predominance.[262-264] The exact incidence of adult LCH is not well established; currently figures stand at 1 to 1.5 cases per million population per year,[265] but this is likely to be an underestimate. In younger patients (0–20 years), the most common sites affected are bone and skin, whereas in older age groups (21–100 years), lung involvement increases dramatically while bone and skin involvement decreases.[264]

Etiology, Pathogenesis, and Cell of Origin

Studies on the pathogenesis of LCH have examined inflammatory and infectious mechanisms, including the role of viruses such as EBV, CMV, Merkel cell polyomavirus, and HHV8.[266,267] Evidence of

the clonal nature of the disease was first shown using HUMARA gene assay,[268] and in 2010, recurrent *BRAF* p.V600E mutations were identified in 57% of archival LCH cases,[243] indicating the neoplastic nature of disorder. It was also shown that the cells in LCH had evidence of MAPK pathway activation regardless of mutational status, a finding also observed in other studies.[269,270] Since then, other non-p.V600E activating alterations have been described in *BRAF*[271] and in other genes of the MAPK pathway, including largely mutually exclusive mutations in *MAP2K1*[269,272] and mutations in *ARAF*.[273] Recurrent mutations in *NRAS*[270,274,275] have mostly been described in pulmonary LCH (PLCH), including concurrent *NRAS* and *BRAF* p.V600E mutations that occurred within distinct lesional cell populations.[270] *KRAS* mutations have been very rarely observed.[270,276]

In tandem with the discoveries related to molecular pathogenesis, there has been progress in the understanding of the cell of origin of the disease. Originally, differentiation from Langerhans cells was postulated because of the immunophenotype (CD1a-positive and langerin [CD207]-positive) and the presence of Birbeck granules in the cells of LCH on ultrastructural examination. Against this, langerin (CD207) expression was also observed in various other dendritic cell subsets,[277] and transcriptional studies showed that the neoplastic cell in LCH was more closely related to immature myeloid dendritic cells than to the hypothesized epidermal Langerhans cell.[278] Furthermore, in a subset of patients, the *BRAF* p.V600E mutation was detected in circulating CD14-positive monocytes and CD11c-positive myeloid dendritic cells, and also in CD34-positive bone marrow progenitors[279] in keeping with origin from a

hematopoietic precursor. This led to the proposition of a model of misguided myeloid dendritic cell differentiation, whereby the stage of development of the hematopoietic cell in which the somatic mutation occurs determines the clinical severity of the disease and its distribution, such that somatic mutation in a hematopoietic stem cell or dendritic cell precursor may determine progression to high-risk disease and mutation in a tissue-restricted dendritic cell progenitor or differentiated dendritic cell may determine multifocal low-risk or single-site disease.[245] However, understanding remains imperfect. There is also evidence for an embryonic cell-of-origin shown by a mouse model in which targeted expression of *BRAF* p.V600E mutation in yolk sac erythro-myeloid progenitors and the resident macrophage lineage results in a neurodegenerative process similar to that of histiocytic disorders.[280]

Studies investigating the mechanisms through which ERK activation in myeloid dendritic cell precursors mediates LCH pathogenesis have identified *BRAF* p.V600E-induced senescence in

hematopoietic progenitors as contributing to LCH pathophysiology[281] and show that extracellular signal-related kinase activity induced by *BRAF* p.V600E inhibits C-C motif chemokine receptor 7 (CCR7)-mediated dendritic cell migration, trapping dendritic cells in tissue lesions. Furthermore, *BRAF* p.V600E increases expression of BCL2-like protein 1 *(BCL2L1)* in dendritic cells, resulting in resistance to apoptosis.[282]

Clinical Features

LCH affects a wide age distribution from neonates to adults, and has a diverse clinical presentation depending on the affected organ systems, ranging from a self-limited course with a single site of involvement to a more aggressive disseminated, multisystem disease.[246]

Single-system LCH (SS-LCH) has one or more LCH lesions that are confined to a single tissue or organ. Multisystem LCH (MS-LCH) shows lesions in two or more organs/systems such as skin, bone, lung, lymph node, spleen, CNS, and liver. Involvement of the liver, spleen, and hematopoietic system in children is associated with an increased risk of mortality[283] and the presence or absence of this "risk organ" involvement further stratifies these patients into high and low risk categories. Recent consensus guidelines on the diagnosis and treatment of adult LCH do not differentiate risk-organ disease as a separate entity because of a lack of current data on prognostic and therapeutic implications in adults, and these guidelines have additionally proposed categories for SS-LCH of unifocal, single-system pulmonary (isolated lung involvement) and

single-system multifocal (more than one lesion involving any organ) LCH in the adult age group.[265]

Involvement of the skin and skeletal system are frequent in LCH, and skeletal manifestations are present in 80% of cases.[144,284] Single-system bone disease in LCH may be unifocal or multifocal, and most often involves the skull vault in children, classically identified as punched-out lytic lesions on plain radiographs (**Fig. 52-8**). Other frequently involved sites include the vertebra, limbs, and pelvis.[285] Lesions may be asymptomatic or can have an associated soft tissue component that may encroach upon surrounding structures. Lesions of the frontal, ethmoid, occipital, sphenoid, zygomatic, and temporal bones have been considered CNS-risk lesions as they seem to be associated with a higher risk of developing CNS-LCH and diabetes insipidus.[283]

Skin involvement by LCH may present in the neonatal period as vesicles and pustules or crusted papulonodular lesions that mostly involve the scalp, face, and trunk and have a tendency to regress spontaneously within weeks or months (congenital self-healing LCH or Hashimoto-Pritzker syndrome). A significant subset of these patients have or will develop multisystem disease, necessitating careful evaluation and follow-up.[286] Other typical cutaneous presentations include an eczematous or seborrheic rash that may be mistaken for cradle cap or for fungal infection if involving intertriginous areas. Gingival lesions, ulceration, and tooth loss may be seen in oral cavity involvement.[287]

Lymphadenopathy related to LCH is most often evident in the cervical lymph nodes.[288] Lung involvement occurs in around 24% of children with multisystem disease[289] and there may be associated

symptomatology, such as cough or shortness of breath, and imaging studies may show blebs, bullae, or fibrosis. Involvement of the hematopoietic system manifests clinically as cytopenias, usually anemia or thrombocytopenia.[283] Liver involvement presents with hepatomegaly (>3 cm below the costal margin at the midclavicular line confirmed by ultrasound) or liver dysfunction.[283] Other organ systems involved include the thyroid, thymus, and gastrointestinal tract. Some patients with MS-LCH may develop HLH.[71]

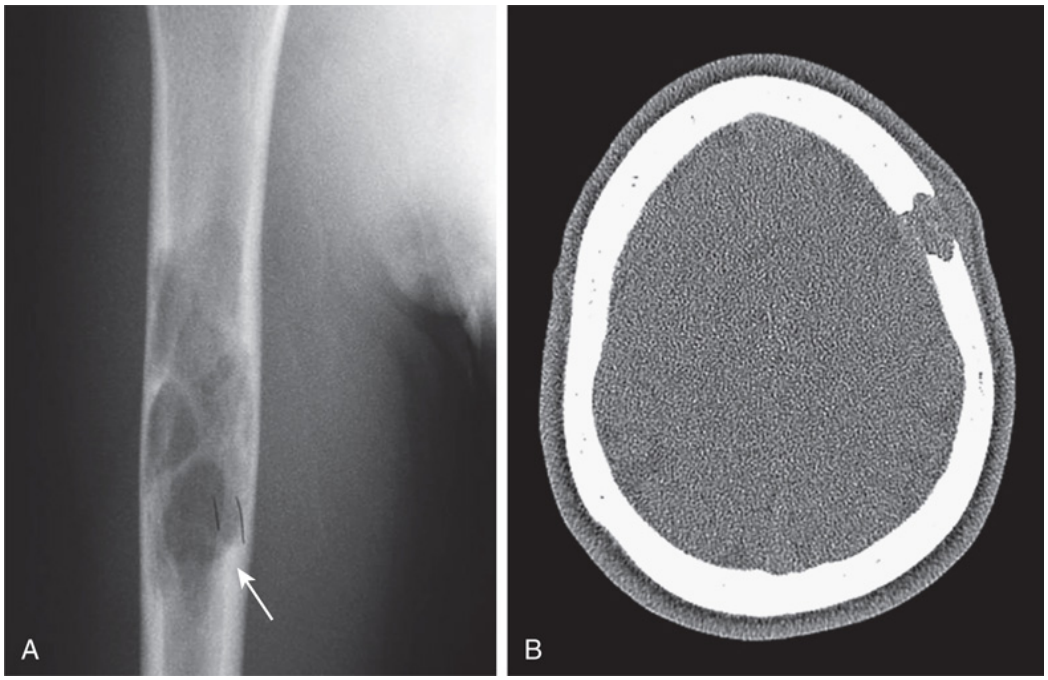

FIGURE 52-8 Langerhans cell histiocytosis in bone.A, Bones of the upper limb have extensive osteolytic changes on radiography. **B,** Computed tomography scan of the head reveals an osseous defect and adjacent soft tissue component.

Neurodegenerative LCH lesions (ND-LCH) are a late-onset complication of LCH manifesting as neurologic symptoms, particularly cerebellar ataxia, neurocognitive impairment, pyramidal signs, pseudobulbar palsy, and psychiatric disorders.[290] The median incidence of clinical ND-LCH is approximately 1 per year, and affected patients have typically been previously treated for a multisystem, risk-organ negative LCH. The presence of the *BRAF* p.V600E mutation is associated with a high risk of development of clinical ND-LCH in patients with pituitary, skull base, or orbit bone involvement.[290] LCH lesions may also present in the CNS, including in the hypothalamic-pituitary region with resultant diabetes insipidus, or as dural masses.[291]

Langerhans Cell Histiocytosis in Adults

LCH in adults presents with a similar symptomatology to childhood cases, although the likelihood of an alternative diagnosis is higher and prognostic stratification according to risk organ status is not currently considered relevant in the adult setting.[265,292] PLCH is commonly a single-system disease in adults, which has a very strong association with smoking and has a peak incidence of between 20 and 40 years of age.[293] There is also a higher incidence of oral and genital mucosa involvement in adults.[294]

Morphology

The histopathologic diagnosis of LCH requires a tissue biopsy showing a population of large (15–25 μm) histiocytic cells with ample eosinophilic cytoplasm and distinctive nuclear features with a complex, folded nuclear outline and often a nuclear groove ("coffee-bean nucleus") (**Fig. 52-9**; **Fig. 52-10A**). The cells are round-to-

oval in shape and do not have the dendritic morphology of admixed inflammatory dendritic cells. Occasional multinucleated giant cells may be present. There is often an associated inflammatory milieu. Eosinophils are commonly present and may form microabscesses. Small lymphocytes and macrophages may be seen; however, plasma cells are typically rare.[2,295] Mitotic activity can be identified, as can focal necrosis; however, the presence of nuclear pleomorphism, frank cytologic atypia, and atypical mitoses should prompt consideration of Langerhans cell sarcoma (LCS), particularly in older patients.

Immunophenotype

The phenotype of LCH is characterized by the expression of S100 (nuclear and cytoplasmic), CD1a (surface and paranuclear), and langerin (CD207) (granular cytoplasmic), which correlates with Birbeck granule formation, replacing the requirement for ultrastructural examination (**Fig. 52-10B**; **Fig. 52-11**).[283] LCH cells show Golgi expression of CD68, but are usually negative for other monocytic and macrophage markers, including CD14, OCT2, and CD163.[265] Most cases show strong cyclin D1 expression in contrast to reactive Langerhans cell populations.[296]

In cases harboring a *BRAF* p.V600E mutation, IHC using the mutant-specific antibody clone VE1 shows moderate to strong cytoplasmic staining in mutated cells. However, the immunostaining has variable sensitivity and specificity in tissue biopsies based on the cellularity of the tumor and staining intensity; therefore, it is currently recommended to confirm any negative or equivocal results

by molecular methods such as *BRAF* p.V600E allele-specific PCR.[242,265]

Histopathologic Features and Differential Diagnosis in Various Sites of Involvement

LCH can usually be separated from other forms of histiocytosis on the basis of histomorphology and immunophenotype, although care must be taken in small biopsies to avoid over-interpretation of perilesional macrophage infiltrates as non-LCH neoplasia (**Table 52-3**).

Bone

LCH in bone usually manifests as a lytic lesion composed of sheets of atypical cells with the diagnostic immunophenotype within an inflammatory background including eosinophils and osteoclast-like giant cells. There can be associated cortical destruction and necrosis and hemorrhage may be present. Some cases can show aneurysmal bone cyst-like features (**Fig. 52-12**).[297]

In long-standing lesions and lesions with an associated fracture, extensive fibrosis or xanthomatous changes may supervene and the LCH cells may be few or absent, precluding definitive diagnosis.[298] Distinction of LCH from reactive conditions such as chronic recurrent multifocal osteomyelitis may be challenging on the basis of histopathology in these cases; however, correlation with the entire clinical and radiologic picture should raise the suspicion of LCH. Prominent xanthomatous changes may raise the consideration of other histiocytic neoplasms, such as ECD. Radiologic findings may suggest other diagnoses. In children, other bone tumors, such as osteosarcoma or Ewing's sarcoma, may be considered and in adults,

plasma cell neoplasia or metastatic tumor may be within the differential diagnosis.

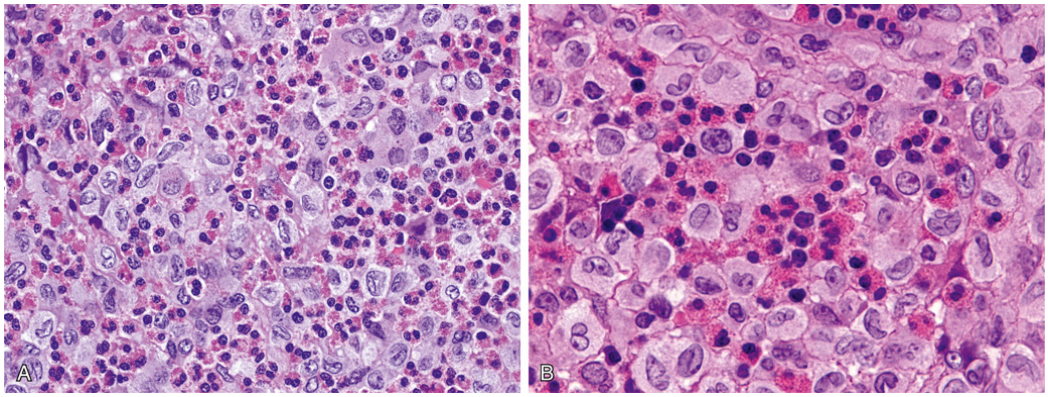

FIGURE 52-9 Langerhans cell histiocytosis.A–B, Langerhans cells have eosinophilic cytoplasm and distinctive nuclear features with a complex, folded nuclear outline and often a nuclear groove. Eosinophils are often abundant in the background and may form microabscesses.

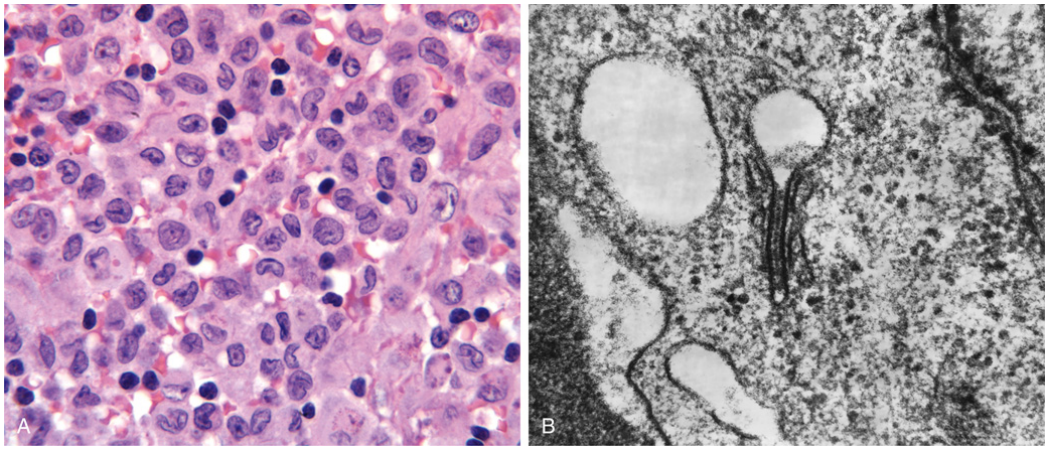

FIGURE 52-10 Langerhans cell histiocytosis in soft tissue.A, LCH cells have complex folded and grooved nuclei but limited pleomorphism. **B,** Electron microscopy reveals peripheral Birbeck granules, pentalaminar structures with a zipperlike appearance and a terminal bulbous swelling.

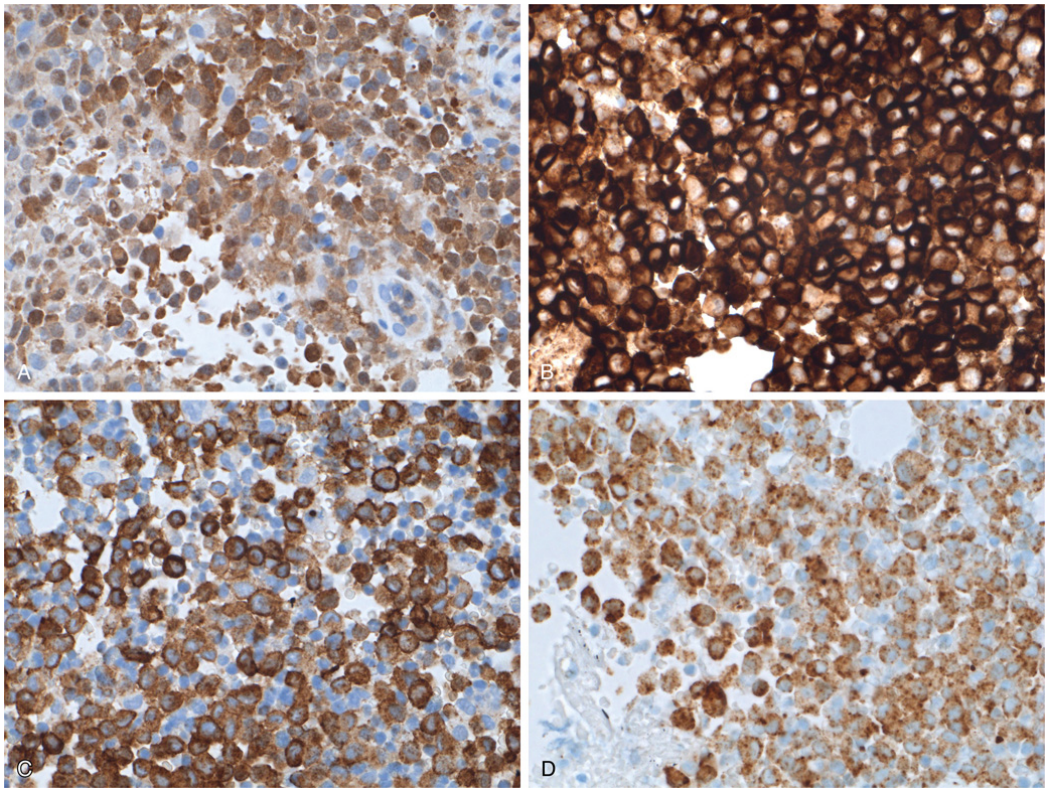

FIGURE 52-11 Langerhans cell histiocytosis. The cells express S100 **(A)**, CD1a **(B),** and langerin **(C)**. Immunohistochemistry with *BRAF* p.V600E-specific antibody is also positive **(D)**.

Skin

Cutaneous involvement by LCH is characterized by infiltration of the upper papillary dermis by sheets of the atypical cells (**Fig. 52-13**). Epidermotropism with surface ulceration and epidermal inflammatory changes may be present, and there may be associated eosinophils. Xanthomatous changes are rare but may be seen in late LCH lesions and mimic juvenile xanthogranuloma (JXG).[299] The histologic differential diagnosis includes other neoplastic and inflammatory processes. Other types of cutaneous histiocytic lesions can generally be excluded on immunophenotypic grounds. Neoplasia of other lineages such as cutaneous melanocytic lesions or cutaneous mastocytosis can be differentiated by their negativity for CD1a and langerin (CD207) and expression of other markers such as MelanA and HMB45 (melanocytic lesions) or mast cell tryptase and CD117 (mastocytosis). Cutaneous involvement by myelomonocytic neoplasms presents a potential pitfall,[300] as LCH can be associated with leukemic malignancy. Inflammatory dermatoses due to various causes may show hyperplasia of CD1a-positive dendritic cells, which can be distinguished from LCH by the spindled morphology of the cells and the more variable expression of langerin (CD207).

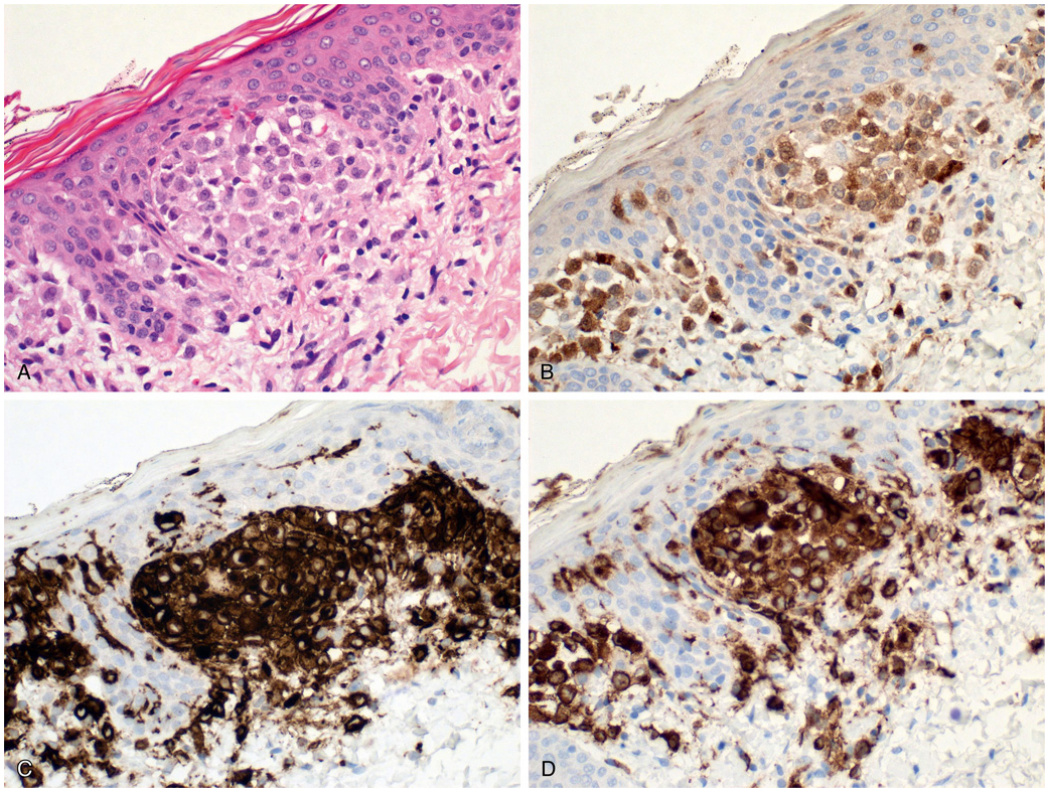

FIGURE 52-13 Langerhans cell histiocytosis in skin. There is infiltration of the upper papillary dermis by sheets of the atypical cells **(A)** that express S100 **(B)**, CD1a **(C),** and langerin **(D)**.

Lymph Node

Lymph nodes involved by LCH show sinusoidal infiltration by LCH cells, eosinophils, and other associated inflammatory cells (**Fig. 52-14**). Osteoclast-like multinucleated giant cells and small foci of necrosis can also be present. Occasionally, there may be total effacement of the nodal architecture with paracortical infiltration.[288] The sinusoidal pattern of involvement is key to the distinction of LCH from reactive nodal processes containing Langerhans cells, such

as dermatopathic lymphadenitis.[301] Dermatopathic lymphadenitis shows prominent paracortical infiltration by a mixture of dendritic cells and Langerhans cells in contrast to the sinusoidal clusters of LCH cells that are present in LCH.[302] Nodal involvement by other types of neoplasia may also enter the differential diagnosis. Anaplastic large cell lymphoma can show an intrasinusoidal pattern of lymph node involvement; however, it can be distinguished by CD30 expression and negativity for CD1a and langerin (CD207). LCH can co-occur with other neoplastic processes in lymph nodes; therefore, thorough evaluation is necessary so as not to overlook an associated second pathology such as classic Hodgkin lymphoma or metastatic thyroid carcinoma.

Lung

Early lesions of PLCH show cellular bronchiolocentric nodules composed of Langerhans cells and an admixed infiltrate of lymphocytes, eosinophils, plasma cells, and neutrophils associated with destruction of bronchiolar wall and adjacent lung parenchyma.[303] The differential diagnosis of PLCH includes respiratory bronchiolitis and desquamative interstitial pneumonia, hypersensitivity pneumonitis, and other histiocytosis, particularly ECD.

Late lesions of PLCH show bronchiolocentric stellate scars and cysts (**Fig. 52-15**). Langerhans cells might not be detectable in late lesions and histologic distinction from other causes of fibrosing cystic disease may not be possible, though LCH may be suspected based on imaging findings.

Central Nervous System

CNS disease can be tumorous or neurodegenerative, and the histopathologic diagnosis of CNS-LCH may be challenging because of difficulty in obtaining substantial tissue biopsies and the potential to misinterpret adjacent perilesional inflammatory changes as other forms of histiocytosis. Tumor lesions involve the hypothalamic-pituitary axis and extraaxial sites including the meninges and choroid plexus. Intraparenchymal involvement is rare. Histopathology shows a mixed infiltrate of histiocytes, foamy macrophages, and multinucleated giant cells, as well as eosinophils, lymphocytes, and plasma cells.[304] The presence and number of CD1a-positive cells within lesions is variable, and these may be scarce. The differential diagnosis includes other histiocytic disorders such as JXG, ECD, and RDD, and also lymphoma, craniopharyngioma, and other metastatic lesions.

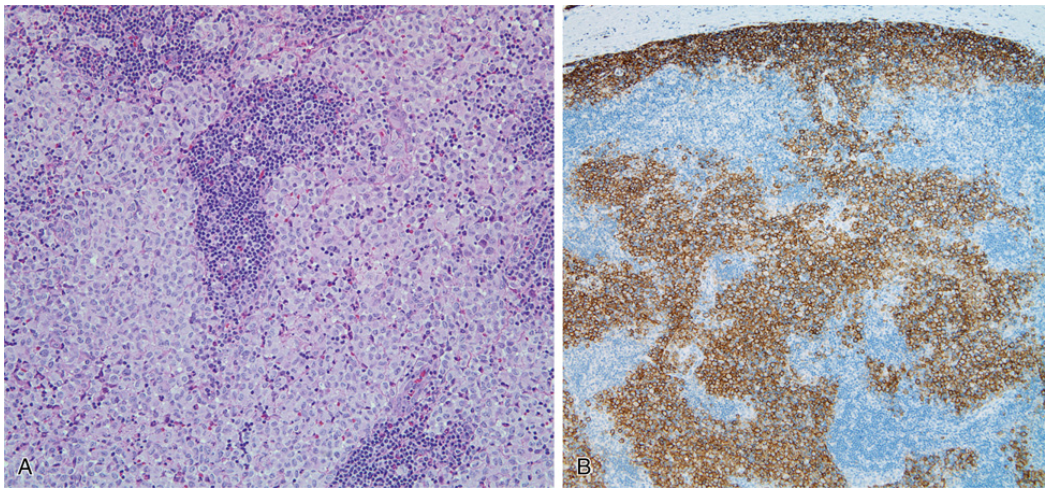

FIGURE 52-14 Langerhans cell histiocytosis, lymph node.A, When the node is replaced, the sinus pattern, characteristic of LCH involvement, is obscured. **B,** CD1a (and CD207) will generally reveal the sinus pattern. CD1a and CD207 can be absent or low on the infiltrating paracortical cells.

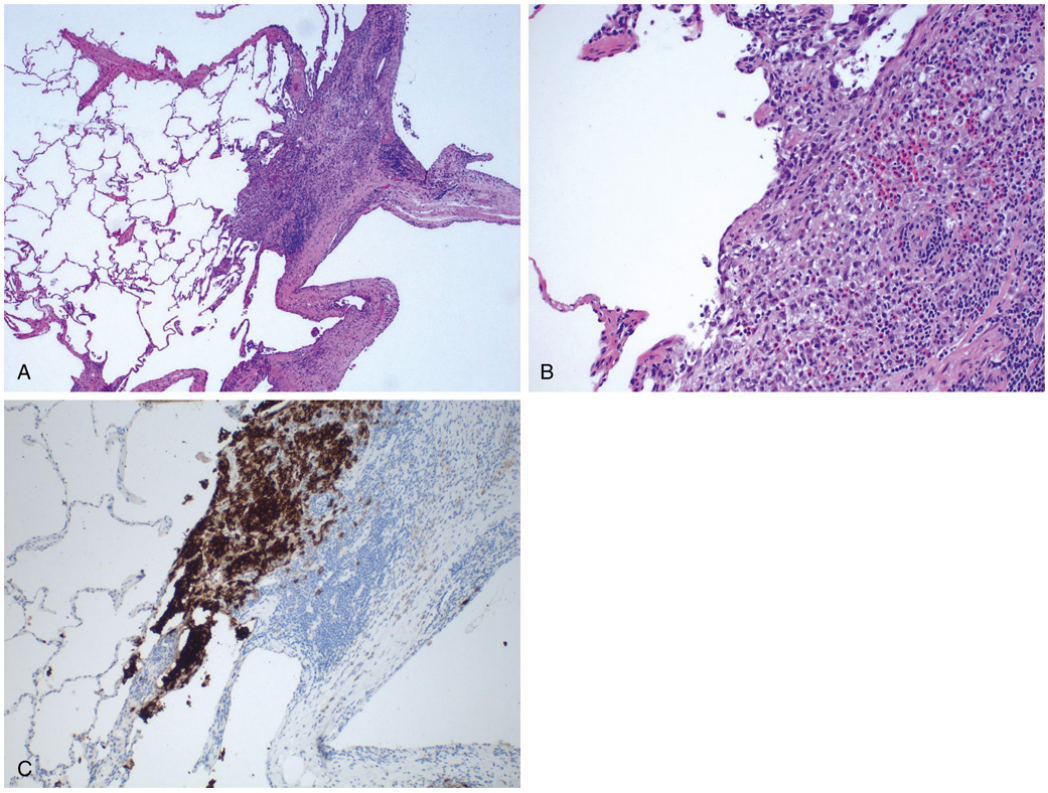

FIGURE 52-15 Pulmonary Langerhans cell histiocytosis.A, Lung parenchyma with an area of stellate scarring and cyst formation. Langerhans cells are focally present **(B),** expressing CD1a **(C)**.

Neurodegenerative lesions mainly affect the cerebellum and are characterized by diffuse parenchymal inflammation associated with neuronal and axonal degeneration, and secondary myelin loss.[304] ND-LCH was originally considered a paraneoplastic process; however, migration of *BRAF* p.V600E mutated langerin/CD207-negative hematopoietic precursors to specific regions of the brain has recently been implicated in driving the neurodegenerative process.[305]

Liver

Liver biopsy taken at an early stage in the disease course may show a lobular infiltrate of LCH cells with the typical immunophenotype. These can form focal aggregates and are mixed with lymphocytes. Eosinophils and neutrophils may also be present. As the disease progresses, the bile ducts may be infiltrated and the appearance may resemble a sclerosing cholangitis. At this stage, LCH cells may not be easily identifiable, and the diagnosis of LCH may not be initially considered on histopathology without the appropriate clinical information.[306] The histologic findings of hepatic LCH may resemble primary sclerosing cholangitis or primary biliary cirrhosis. If granulomatous inflammation is present, an infectious etiology or sarcoidosis may be considered initially.

Bone Marrow

Involvement of the hematopoietic system or bone marrow is defined clinically by the detection of anemia or thrombocytopenia.[283] Histologic examination of the marrow has limited sensitivity, as CD1a-positive LCH cells are not often encountered, even in the presence of cytopenias,[307] although histiocytic aggregates and other features such as megakaryocyte hyperplasia and myelofibrosis may be present. A recent study has shown that measurable bone marrow disease may be detected more reliably by allele-specific ddPCR than by CD1a or *BRAF* p.V600E immunostaining.[308]

Thymus

LCH may involve the thymus as SS-LCH or as part of MS-LCH disease and presents with a solid or cystic mediastinal mass. The

architecture of the gland can be replaced or disrupted by nodules of LCH with fibrosis, multinucleated giant cells, and eosinophils, or changes may be mostly confined to the medulla. There can be areas of necrosis and calcification. In rare cases, a mixed histiocytosis is present, including components of LCH and JXG.[309] Thymectomies may also show incidental small foci of Langerhans cell hyperplasia that are not sufficient to be diagnostic of LCH.[309]

Genetics and Molecular Findings

As previously noted, recurrent activating alterations in genes of the MAPK pathway are found in the majority of LCH cases. *BRAF* p.V600E[243,310] mutations are the most frequent, identified in ~50% of cases, but other alterations in *BRAF,*[271] including *BRAF* p.N486_P490del[271,274,311] and alterations in *MAP2K1,*[269,272] are recurrently present. *BRAF* and *MAP2K1* alterations appear to be mostly mutually exclusive,[269] although rarely co-occur.[312] Mutations in *NRAS* are very rare outside of PLCH, and occasionally have been found to co-occur with *BRAF* p.V600E mutations in both PLCH and non-PLCH. In PLCH, it is suggested that the mutations are carried by different subclones of the tumor.[270] *KRAS* mutations are rare overall in LCH with only a very small number of cases reported.[274,275,311] Infrequently, mutations have also been found in *ARAF* and *CSF1R*[273,275] and a *PIK3CA* mutation was detected in a single case.[313]

Activating *BRAF* fusions have been identified with different partner genes *(BICD2, CSF2RA, PACSIN2, SPPL2A, LMTK2, FAM73A).*[271,275,314] Case reports have also detailed single findings of other fusions in LCH including *PLEKHA6::NTRK3*[315] and

ETV3::NCOA2,[311] which has also been identified in a small number of indeterminate dendritic cell histiocytosis (IDCH) cases.

Association With Malignancy

Solid cancers, lymphomas, and other hematologic malignancies seem to show a higher incidence in patients with LCH compared with the general population.[316] In children, most associated malignancies are leukemia (mainly acute myeloid leukemia) and myeloproliferative disorders, whereas in adults solid cancers and lymphoma are more common.[317] Lung, thyroid, and breast cancers are the most frequently occurring solid malignancies.[316,317] Synchronous *BRAF* p.V600E mutated papillary thyroid carcinoma and LCH has been reported.[318] Cases of LCH concomitant with or subsequent to classic Hodgkin lymphoma, T-lymphoblastic lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma, and follicular lymphoma (FL) are also described. In some cases, a clonal relationship between the disorders has been shown; in others, the LCH population is postulated to be incidental.[319,320]

Clinical Course and Prognosis

LCH has a low overall mortality but a high relapse rate, with the disease course generally depending on the disease extent and sites of involvement. The clinical presentation appears to associated with the particular MAPK-activating mutation detected, with *BRAF* p.V600E mutated LCH presenting at a lower age and with a higher prevalence of MS-LCH, high-risk disease, and skin involvement, whereas *MAP2K1* alterations are associated with a higher prevalence of SS-bone LCH, and *BRAF* exon 12 deletions appear to correlate with lung involvement.[321]

Treatment decisions in LCH are made based on sites and extent of disease. For patients with SS-LCH disease and no involvement of critical organs such as the CNS, heart, liver, or spleen, treatment may be limited to observation or local therapy. Curettage or radiotherapy can be considered for localized bony lesions and topical therapies, oral methotrexate and 6-mercaptopurine may be used in isolated skin involvement.[242,265,322] Some cases of PLCH may resolve with smoking cessation, but others may benefit from treatment with high-dose prednisone or systemic therapy if disease is progressive.[242,265] Lung transplantation may be considered in advanced, refractory cases.

Systemic therapy can be required for the treatment of MS-LCH, multifocal SS-LCH, or unifocal LCH with critical organ involvement. Chemotherapy with vinblastine and prednisone is generally used in the pediatric setting.[322] Notably, pediatric chemotherapy regimens cause greater toxicities in adults, and initial treatment with cytarabine or cladribine may be preferable in adults.[242,265] In adults with LCH and CNS lesions, first-line treatment with MAP kinase inhibitors, cladribine or cytarabine (with methotrexate) is preferred.[242,265] Recent studies have reported on the use of targeted therapy, particularly BRAF inhibitors, in LCH in adults and in the setting of refractory LCH in children. Most patients have shown a good clinical response, but the majority experience disease reactivation upon discontinuing therapy.[323,324]

Indeterminate Dendritic Cell Histiocytosis

Definition

IDCH is an extremely rare tumor that shows immunophenotypic overlap with LCH (S100-positive/CD1a-positive), but does not express langerin (CD207) or contain Birbeck granules on ultrastructural examination.[325]

Synonyms and Related Terms

Indeterminate dendritic cell histiocytosis (ICC); Indeterminate dendritic cell tumor (WHO 5th ed.); Indeterminate dendritic cell tumor (WHO Revised 4th ed.); Indeterminate cell histiocytosis (Revised Classification of the Histiocyte Society, 2016); Primary/secondary malignant histiocytosis, indeterminate cell subtype (Revised Classification of the Histiocyte Society, 2016).

Epidemiology

IDCH is rare. In a review of ~85 cases published in the literature between 1985 and 2016, IDCH was found to affect all ages with a median age of 45 (range 0–87 years) and to show a slight male predominance (M:F ratio 1.2:1).[326]

IDCH has been observed either subsequent to or in association with diverse hematologic malignancies (reported as accounting for ~22% of cases in one review[327]), including angioimmunoblastic T-cell lymphoma (AITL),[328] mycosis fungoides,[329] FL,[325] T-lymphoblastic lymphoma,[330] B-lymphoblastic lymphoma,[331] chronic lymphocytic leukemia/small lymphocytic lymphoma,[332] and unspecified low-grade B-cell lymphoma,[333] as well as chronic myelomonocytic leukemia (CMML),[334-336] MDS,[337] acute myeloid leukemia,[338] and mast cell leukemia.[339] The IDCH may precede the diagnosis of a myeloid neoplasm by some time.[338,339] The nature of

the relationship between the IDCH and associated hematologic malignancy has not been established in many cases.

Clinical Features

Most of the cases reported in the literature have shown cutaneous involvement, usually presenting with single to multiple skin nodules and papules, although patches or plaques may also occur and disseminated involvement may be present.[326,327,340] Extracutaneous involvement is very uncommon but has been reported with lymph node,[328] pancreatic,[341] bone,[342,343] and splenic[344] involvement. Rarely, multisystem disease can occur.[345]

Morphology

The tumor cells show a histiocytoid morphology with round-to-elongated nuclei and may show occasional nuclear grooves, but eosinophils are not prominent, and cutaneous cases usually lack epidermotropism.[327] Cytologic appearances can be variable (**Fig. 52-16A**). Some cases, particularly those associated with CMML, may show marked atypia with blastic cytologic features.[336]

Immunophenotype

IDCH expresses CD1a and is usually positive for S100 with variable expression of CD68, but is negative for langerin (**Fig. 52-16B–D**).[327] CD163 may be rarely expressed, and CD56 positivity has been described in lesions with an IDCH immunophenotype, often in the setting of an associated myeloid neoplasm.[325,334,336]

Genetics and Molecular Findings

Molecular analysis has not been performed in most of the reported cases. An *ETV3*::*NCOA2* fusion has been documented in five cases[346-348] without a reported associated hematologic malignancy and a *BRAF* p.V600E mutation has been reported in another case.[343]

Some secondary cases of IDCH have been shown to be clonally related to the associated hematologic malignancy. A number of cases associated with CMML have shown shared mutations in both tumors, such as a shared *TET2* mutation,[349] shared *TET2, ASXL1,* and *ZRSR2* mutations,[350] and shared MAPK mutations, including in *KRAS* p.G12R[334] and *NRAS* p.G12V.[351]

Identical cytogenetic abnormalities have also been discovered in some cases, also supporting a common cell of origin. Trisomy 8 was detected in both CMML and IDCH samples in one report,[336] and a further case showed trisomy 12 in both T-ALL and IDCH components.[330] Another T-ALL–associated IDCH showed loss-of-heterozygosity on chromosome 9p with deletion of *CDKN2A* in both the T-ALL and IDCH, but also showed evidence of clonal divergence with the acquisition of a *KRAS* mutation in the IDCH component and a *TP53* mutation in the T-ALL, among other differing cytogenetic findings between the two lesions.[352]

BRAF p.V600E expression has been shown by IHC in a case associated with AITL[328] and has been found by sequencing in a case associated with both low-grade B-cell lymphoma and CMML, in addition to *TP53* and *RUNX1* mutations.[333] The t(14;18) was detected in an IDCH in which there was a previous history of FL.[325] A patient with unexplained systemic lymphadenopathy also had a clonal IG rearrangement detected in an excised IDCH.[325]

Clinical Course and Prognosis

The clinical behavior is variable. Isolated skin lesions usually have an indolent clinical course, and some cases may spontaneously regress[353]; however, a fatal clinical course has been described.[345] IDCH in the setting of CMML may exhibit more aggressive clinical behavior.[336,349]

Skin lesions have been managed with excision, UV-B phototherapy, or electron beam therapy. Some cases have been treated with thalidomide or methotrexate, and other chemotherapeutic agents have also been used, mainly in cases associated with hematologic malignancy.[326,327] A significant response to therapy with a BRAF inhibitor was obtained in one case.[343]

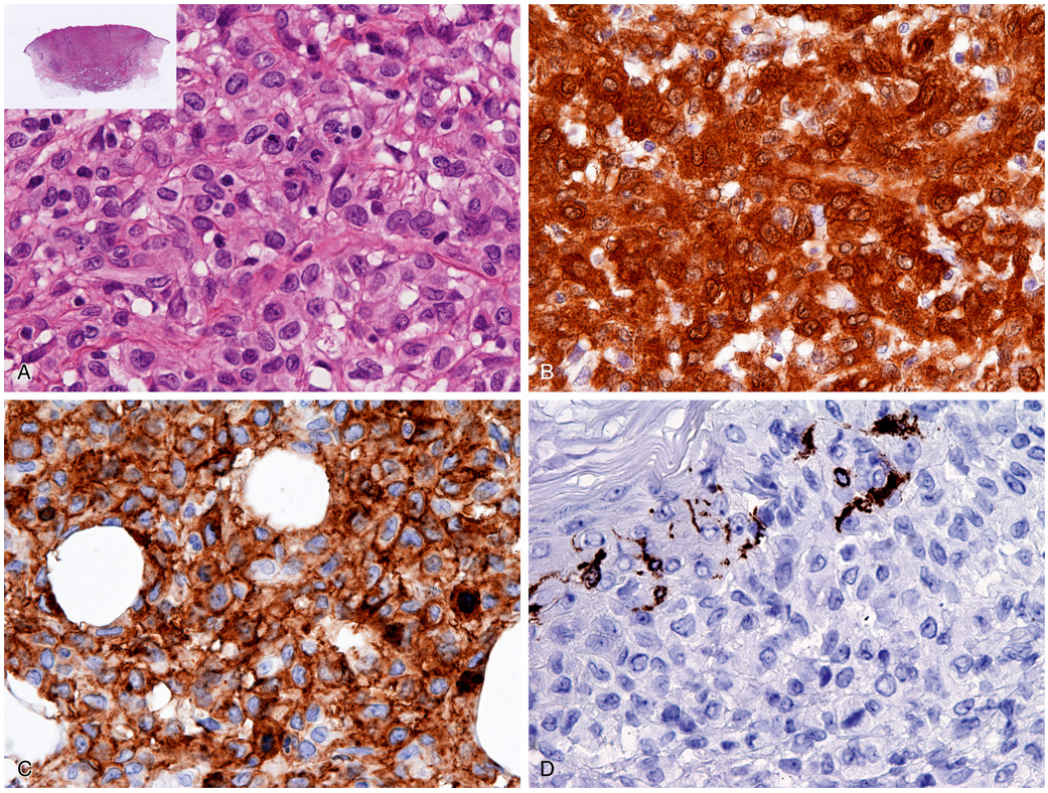

FIGURE 52-16 Indeterminate dendritic cell histiocytosis. The cytologic features may be variable. **A,** This is a skin lesion showing cells with a histiocytoid morphology with round-to-elongated nuclei and occasional nuclear grooves. Eosinophils are not prominent. They express S100 **(B)** and CD1a **(C)**, but are negative for langerin **(D),** which highlights the intraepidermal Langerhans cells.

Differential Diagnosis

The major differential diagnosis is with other histiocytic tumors, which can be distinguished by IHC. Given the association with both lymphoid and myeloid neoplasms, further patient evaluation may be

necessary to exclude systemic involvement by another hematologic malignancy.

Dermal infiltrates that are rich in indeterminate cells have also been described after tick or mosquito bites or post scabies infection, and may resolve spontaneously or with steroid therapy.[354]

Erdheim-Chester Disease

Definition

ECD is a rare multisystem clonal histiocytic disorder with distinct clinical and imaging features that is histologically characterized by a xanthomatous histiocytic infiltrate associated with variable inflammation and fibrosis, and driven by activating alterations in the MAPK pathway.

Synonyms and Related Terms

Erdheim-Chester disease (ICC); Erdheim-Chester disease (WHO 5th ed.); Erdheim-Chester disease (WHO Revised 4th ed.); Erdheim-Chester disease (Revised Classification of the Histiocyte Society, 2016).

Background and Pathogenesis

ECD was first described in 1930 as *Über Lipoidgranulomatose* by Jakob Erdheim and William Chester.[355] Since then, more than 1500 cases have been reported in the literature,[144] the majority in recent years, as greater awareness of the condition has led to an increase in diagnosis.

The pathogenesis of ECD has been a subject of debate, with initial discourse centered on whether it represented an inflammatory or neoplastic condition. Studies have described proinflammatory

mediators and cytokine perturbations in the lesions and sera of ECD patients,[356,357] but the pathogenesis remained unclear until 2012 when *BRAF* p.V600E mutations were discovered in the majority of cases.[310,358] ECD was subsequently classified as a neoplasia by the WHO in 2016[295] and in the revised classification of histiocytoses and neoplasms of the macrophage-dendritic cell lineages from the Histiocyte Society[2] within the category of L type histiocytosis owing to the molecular overlap with LCH and the not-infrequent co-occurrence of the two disorders, so-called "mixed histiocytosis." Cases of extracutaneous JXG with MAPK pathway mutations and tumors with a JXG-like morphology harboring ALK fusions (ALK-positive histiocytosis) also fall under ECD in the revised classification of the Histiocyte Society; however, ALK-positive histiocytosis is now accepted as a distinct entity in the ICC[240] and in the WHO 5th edition.[241]

A complex cytokine and chemokine network is established within ECD lesions, resulting in the recruitment and activation of macrophages and T cells.[359] Studies using the *BRAF* p.V600E specific IHC antibody have shown that the oncogenic *BRAF* p.V600E mutation in the tissue infiltrate of ECD lesions localizes to a subset of the histiocytic population.[360] A number of mechanisms have been proposed as a link between the oncogenic mutation and the observed inflammatory activation, including oncogene-induced senescence, a major protective response against oncogenesis that is characterized by cell cycle arrest and upregulation of tumor suppressor proteins, including p16 and p21,[359-361] and oncogene-induced activation of trained immunity, a proinflammatory program.[362]

Epidemiology

ECD is primarily a disease of adults, with a male predominance of about 3:1 and mean ages at presentation of 46 and 56 years in two different cohorts.[363,364] Pediatric cases are described, but are rare.

Clinical Features and Imaging Findings

ECD is a chronic and multisystem disorder with a variety of clinical manifestations depending on the organ system involved. The vast majority of patients have bone involvement (80%–95%)[363,364] and many experience bone pain (40%–50%),[363] with the classic imaging appearance showing symmetric long bone osteosclerosis, often in the distal femur and tibia. In contrast to LCH, lesions are usually osteosclerotic rather than osteolytic, and involvement of the skull and axial skeleton occurs less frequently.[365] CNS disease has been reported in 37% to 40%,[363,364,366] and up to 90% of patients may experience neurologic symptoms.[363] ECD typically involves the posterior fossa brain parenchyma, but also occurs in the pituitary and dura. About 28% to 47% may have diabetes insipidus, which can have an onset prior to the diagnosis of ECD.[363,364] Retro-orbital involvement occurs in 22% to 30%.[363,364,366] Cardiac involvement in the form of right atrioventricular pseudotumor is reported in approximately 40%.[363,364] Circumferential encasement or soft tissue sheathing of the thoracic or abdominal aorta and its branches, so-called “coated aorta,” can be detected on imaging in 46% to 62%,[363,364] and may be asymptomatic or result in vascular compromise such as arterial stenosis. Retroperitoneal and perinephric infiltration with the radiologic appearance of “hairy kidney” are also frequent (58%–65%) and may result in hydronephrosis. Cutaneous involvement most commonly occurs as

xanthelasma around the eyelid region (27%–33%).[363,364] Pulmonary involvement can be apparent as interstitial fibrosis on CT scan, although patients are often asymptomatic.[363,367] ECD can also involve the bone marrow, and there is a high prevalence of myeloid neoplasia in patients with ECD.[368,369]

Morphology

The classic histologic appearance of ECD is tissue infiltration by xanthomatous histiocytes with bland nuclear features and abundant foamy cytoplasm.[363] Touton-type giant cells are also present within the infiltrate and there may be an associated densely fibrotic stroma (**Fig. 52-17A–B**). There is often an admixed inflammatory infiltrate of plasma cells, lymphocytes, and occasional neutrophils.[370] The typical histopathology of ECD is indistinguishable from JXG.[371]

The pattern of histologic involvement varies depending on the site biopsied. Bone lesions typically show fibroxanthomatous replacement of the marrow spaces; however, in later fibrotic lesions, the histiocytes may be fewer in number, with an amorphous lipid-laden or granular appearance and lacking the typical xanthomatous morphology.[370] Retroperitoneal lesions may show a prominent plasma cell infiltrate that may be rich in IgG4-positive plasma cells, presenting a diagnostic pitfall.[365] Lesions of the CNS often do not show the characteristic morphologic features, instead showing perivascular lymphocytic infiltrates with a histiocytic component present as individual cells or small aggregates of nonlipidized cells with pale or eosinophilic cytoplasm and indistinct cell borders.[370] Lung involvement is typically characterized by thickening of the

pleura, interlobular septa, and perivascular interstitium by fibrosis and a histiocytic infiltrate with a lymphangitic distribution.[370]

Immunophenotype

The histiocytes of ECD express CD68, CD163, CD14, and factor XIIIa,[363] and are negative for CD1a and langerin (CD207).[370] Variable S100 positivity may be seen[370] (**Fig. 52-17C–E**). IHC with *BRAF* p.V600E-specific antibody may be positive in *BRAF* p.V600E mutated cases; however, it may only stain scattered cells, therefore negative or equivocal results by IHC should be confirmed by molecular analysis[366,370] (**Fig. 52-17F**). PD-1 or PD-L1 are variably expressed in ECD, with PD-L1 positivity significantly associated with an absence of *BRAF* p.V600E mutation in one study.[372]

Diagnostic Criteria

Traditionally, the diagnosis of ECD has required the combination of the classic histologic appearances of a xanthomatous histiocytic infiltrate with the appropriate immunophenotype and the presence of the characteristic radiologic findings, namely symmetric osteosclerosis of the metadiaphysis of the lower-extremity bones on imaging studies.[365] However, the typical histiocyte morphology may not always be present,[370] and a small percentage of patients may not have the characteristic bone lesions on imaging[363,365]; thus, it is of paramount importance to consider the clinical, imaging, and molecular findings in their entirety to reach a final diagnosis. In the absence of bone lesions, ECD should only be considered in the setting of suggestive histopathology and highly characteristic nonosseous lesions on imaging studies, ideally with supportive mutational data. A diagnosis of ECD should also still be considered if

characteristic clinical and radiologic features are present, even when tissue biopsy does not demonstrate classic morphologic features.[365]

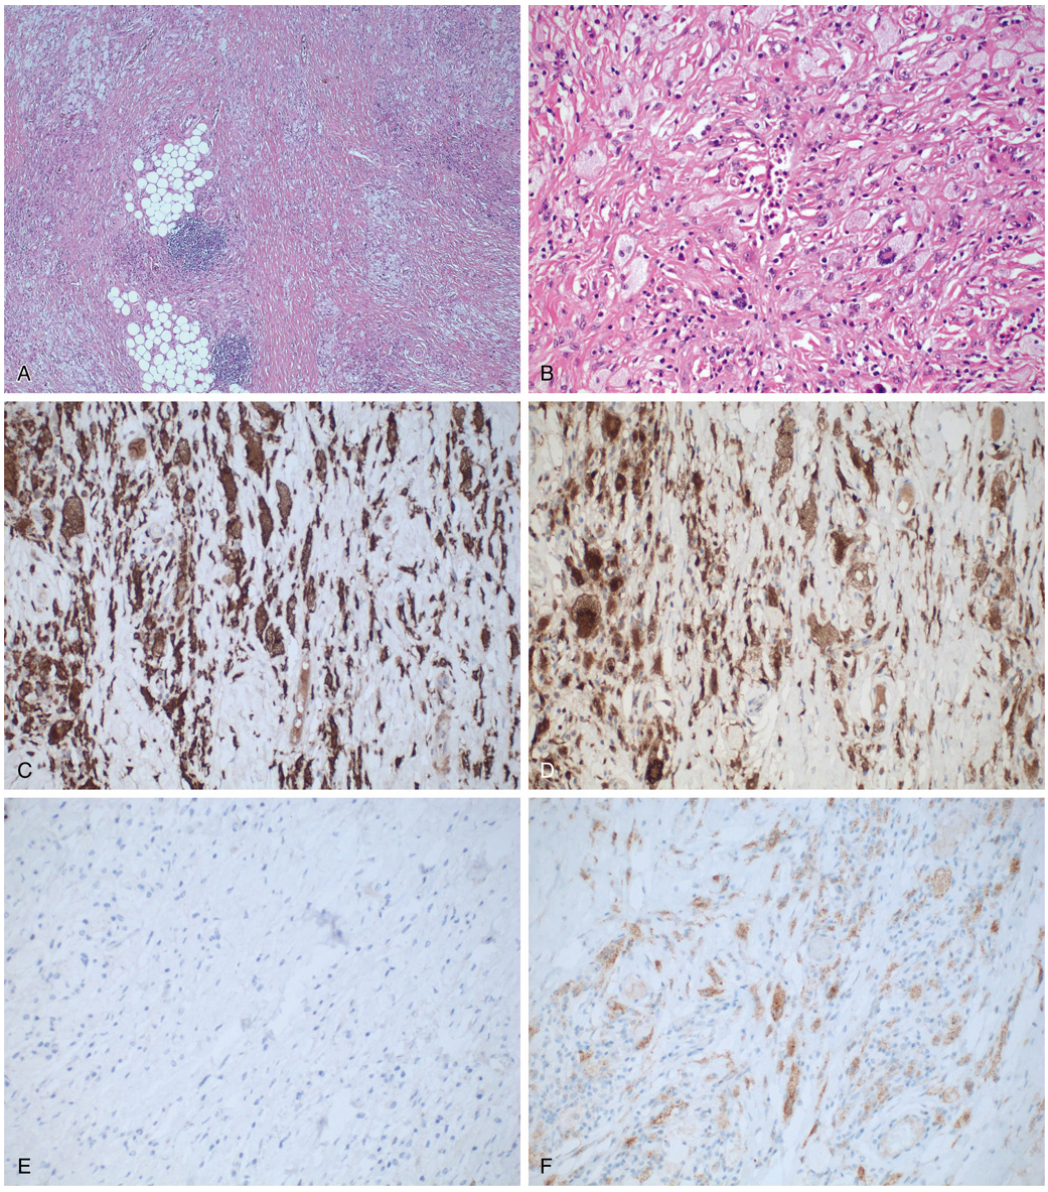

FIGURE 52-17 Erdheim-Chester disease.A–B, There is a densely fibrotic stroma with infiltration by xanthomatous histiocytes with bland nuclear features and abundant foamy cytoplasm. Touton-type giant cells are also present. The histiocytic cells express CD163 **(C)**, factor XIIIA **(D),** and are negative for CD1a **(E)**.

Immunohistochemistry for *BRAF* p.V600E-specific antibody is positive **(F)**.

Genetics and Molecular Findings

A breakthrough in the diagnosis and pathogenesis of ECD came with the discovery of *BRAF* p.V600E in over half of cases.[310,373] Further studies have confirmed additional alterations in the MAPK and phosphatidylinositol 3-kinase (PI3K)-AKT pathways, including in *BRAF* (non-p.V600E alterations), *MAP2K1*,[275,373] *NRAS*,[313,374] *ARAF*,[275,373] *KRAS*,[275,375] and *PIK3CA*.[313] Recently, mutations in *CSF1R, RAF1,* and *MAP2K2* have also been described.[275] A minority of cases show fusions involving *BRAF (RNF11::BRAF, PICALM::BRAF, ANP32A::BRAF, UBTD2::BRAF)* and *NTRK1 (LMNA::NTRK1)*.[275,376] The novel group of tumors with a JXG-like morphology and harboring fusions involving the *ALK* gene have been previously regarded as a subgroup of ECD but are now the distinct entity of ALK-positive histiocytosis.[377]

Tissue biopsy is essential in all cases of ECD for histologic diagnosis and mutational analysis to allow therapeutic decision-making.[365] Reliable molecular assessment in ECD can be challenging because of low tumor cellularity. IHC with *BRAF* p.V600E-specific antibody is not sensitive or specific as the sole method for *BRAF* p.V600E mutational analysis, and negativity for *BRAF* p.V600E should be confirmed by another high-sensitivity molecular assay as the variant allele frequency may be low.[313] Where sufficient tumor tissue is difficult to obtain, analysis of cfDNA from the peripheral blood may be informative.[378]

Association With Other Conditions

There is a high prevalence of concomitant myeloid neoplasia in patients with ECD or mixed histiocytosis (~10.1%), including concurrent MDS, myeloproliferative neoplasms (MPNs), or MDS/MPN, particularly CMML.[369] Molecular analysis of these cases has shown driver mutations typical of myeloid neoplasia (for example *JAK2* p.V617F and *CALR* mutations) co-occurring with mutations that are commonly seen in histiocytosis (such as *BRAF* p.V600E and *MAP2K1* mutations).[369] The kinase mutations can be shared between both components or may be distinct with potential treatment implications, as paradoxical activation of cytokine signaling can occur in cells bearing kinase mutations other than *BRAF* p.V600E alterations upon exposure to BRAF inhibitors.[369] For this reason, bone marrow biopsy should be considered in ECD in the setting of unexplained cytopenias, cytosis, or monocytosis.[365]

The pathogenic mechanisms underlying development of myeloid neoplasia in ECD are not yet understood; however, a high frequency of clonal hematopoiesis has been reported in ECD patients (42.5%), with the most common mutations identified in *TET2* (22%), *ASXL1* (9%), and *DNMT3A* (8%).[379] Of these patients, 18 (15%) subsequently developed myeloid neoplasms, most often MDS, MPN, and CMML.

Approximately 20% of patients may have a mixed histiocytosis, characterized by co-occurring ECD, LCH, or RDD.[380]

Clinical Course and Prognosis

Most patients with ECD require systemic therapy, although a watch-and-wait approach can be considered in asymptomatic cases with

noncritical organ involvement.[242] Targeted therapy with BRAF inhibitors such as vemurafenib or dabrafenib is effective in patients with *BRAF* p.V600E-mutated ECD. MEK inhibitors may be used in ECD associated with other MAPK pathway mutations, cases where a mutation is not detected, or in instances where testing is not available,[242] and there is potential for other targeted agents depending on the mutational profile.[242,365] A case report has described response to treatment with the *CSF1R* inhibitor pexidartinib in a patient with refractory ECD and an activating, in-frame deletion in the *CSF1R* gene.[381] Conventional therapies that have shown efficacy include IFN-α/PEG-IFN-α and cladribine. Anakinra may be considered in patients with low-volume disease in the bones or retroperitoneum.[365]

The prognosis of ECD is variable. One study of 165 patients has shown a median survival of 162 months with a 5-year survival of 82.7%. Retroperitoneal, lung, and CNS involvement were associated with a worse survival.[364]

Differential Diagnosis

The differential diagnosis varies depending on the age of the lesion and the site biopsied. In bone and retroperitoneum, histology may show extensive fibrosis without an obvious infiltrate of xanthomatous histiocytes, which may lead to the diagnosis of another process, such as osteomyelitis or retroperitoneal fibrosis. In such cases, radiologic correlation and molecular studies can aid in establishing the diagnosis of ECD.

ECD may coexist with other forms of histiocytosis, including LCH and RDD at different sites.[370] Dense lymphoplasmacytic infiltrates

may raise the consideration of IgG4-related disease or extranodal marginal zone lymphoma, particularly in biopsies from orbital and retroperitoneal locations.[370] In biopsies from the CNS, areas of myelin loss associated with perivascular chronic inflammation could raise the consideration of multiple sclerosis.[370] Skin lesions showing features reminiscent of a dermatofibroma have been described,[370] as have panniculitis-like and granuloma annulare-like cutaneous presentations.[382]

Juvenile Xanthogranuloma

Definition

JXG is a non-LCH, forming part of a group of macrophage disorders that are characterized by a CD14-positive/CD163-positive/factor XIIIa-positive immunophenotype. In the revised classification of the Histiocyte Society,[2] the xanthogranuloma family of disorders mainly fall into the C group of cutaneous histiocytoses, with the exception of a subset of extracutaneous JXG harboring activating alterations in the MAPK pathway, which some consider as within the spectrum of ECD (L group).[2] The clinical presentation, imaging studies, and molecular findings are essential in the final classification of these lesions.

Synonyms and Related Terms

Disseminated juvenile xanthogranuloma (ICC Classification); Disseminated juvenile xanthogranuloma (WHO Revised 4th ed.); Juvenile xanthogranuloma (WHO 5th ed.); Juvenile xanthogranuloma (Revised Classification of the Histiocyte Society, 2016).

Background

Early descriptions of JXG have been attributed to Virchow in 1871,[383] to Adamson in 1905,[383,384] and to McDonagh in 1912, who postulated origin from the endothelium of the capillaries (nevoxanthoendothelioma).[383,385] In 1954, Helwig and Hackney noted the fibrohistiocytic nature of the lesion and originated the descriptive term of *JXG*.[386] Since then, origin from the indeterminate cell has been hypothesized[387] and consideration also given to the CD4-positive plasmacytoid "monocyte" as the principal element of JXG, though not further proven.[388] Based on the expression of factor XIIIa, the lesional cells have been postulated to be related to dermal dendritic cells[232,389] and, more recently, dermal macrophages.[390]

Epidemiology

JXG occurs predominantly in early childhood, most often within the first 2 years of life, and may present at birth.[384] There is a male predominance overall,[383,384] and an increased prevalence has been documented in children with neurofibromatosis type 1.[391] A relationship between JXG and the development of juvenile myelomonocytic leukemia in children with neurofibromatosis type 1 has been postulated[392] although not confirmed in subsequent studies.[393] The exact incidence of JXG is not known as regressing, solitary lesions may not be reported, but the relative incidence of the disease was estimated at 0.52% (129 out of 24,600 patients) in the Kiel Pediatric Tumor Registry.[384] Approximately 4% of cases of JXG have systemic involvement,[383] although this figure is higher in neonatal patients and one review has shown a 3:1 female

predominance among neonates with disseminated lesions.[394] Histologically similar lesions can also occur in adults (adult xanthogranuloma).

Clinical Features

Cutaneous JXG most commonly presents as a solitary nodule on the head and neck or trunk in a child under the age of 2 years, but may also present as multiple yellow or brown cutaneous papules.[395] Lesions can arise at any site on the body surface.[384] Systemic or disseminated JXG can involve multiple extracutaneous or visceral sites including deep soft tissue, liver, spleen, lung, eye/orbit, oropharynx, muscles, bone marrow, and CNS.[396] CNS JXG accounts for 1% to 2% of cases.[384] It mostly occurs in children <12 years of age and shows a male predominance.[397] Just over half of cases occurring in the CNS have multiple intracranial lesions or show concomitant systemic lesions,[397] and there is a higher mortality rate in CNS JXG (18.6%[397] compared with 1%–2% overall[384]). Ocular involvement by JXG is rare, occurs mainly in children <2 years of age, and is mostly unilateral and involving the iris and conjunctiva. Ocular involvement can be sight-threatening because of the development of complications such as hyphema and glaucoma.[398]

Similar lesions may also occur in adults ("adult xanthogranuloma"), with adults over the age of 20 years accounting for 27% of JXG cases in one single-center study.[399] Similarly to JXG in younger patients, cutaneous involvement of the head and neck predominates in the adult population, and systemic involvement is rare.[399]

Morphology

The histologic features of the xanthogranuloma family of lesions are variable and have been proposed to follow a time-dependent course with “early,” “classic,” and “late transitional” patterns representing time points in the continuous maturation of the lesional cells. A combination of these histologic patterns is often present within a single lesion.[384] JXG and ECD are morphologically and immunophenotypically similar, with the distinction between the disorders made on clinical, molecular, and radiologic grounds.

Early JXG is composed of a sheet-like infiltrate of small-to-intermediate-sized mononuclear histiocytes with sparse to moderate pale eosinophilic cytoplasm and small, round-to-ovoid and sometimes indented nuclei containing an inconspicuous nucleolus. Touton-type giant cells are generally absent. Mitotic figures are present and the mitotic activity is highest in this subtype, but nuclear atypia or atypical mitoses are lacking.

Classic JXG lesions contain histiocytes with more abundant and foamy cytoplasm and, in most cases, contain a population of irregularly distributed giant cells, including “early” Touton giant cells with multiple centrally grouped nuclei, but without surrounding foamy cytoplasm, and typical Touton giant cells with a rim of foamy cytoplasm surrounding a ring of nuclei and central eosinophilic core (**Fig. 52-18A**).

The late transitional pattern shows a predominance of spindle-shaped cells resembling benign fibrous histiocytoma but with focal foamy histiocytes and giant cells.

Cutaneous JXG involves the skin and the adjacent subcutaneous fat, but isolated lesions in deeper soft tissues, including skeletal muscles, are not uncommon, occurring in 14.7% to 16%.[383,384]

Inflammatory cells, in particular eosinophils, may be present in the background with lymphocytes and, rarely, plasma cells. As mentioned, mitotic activity may be present, more often in soft tissue JXG than in the cutaneous form.[383]

Immunophenotype

Lesions of JXG show membranous staining for CD163 and CD14 and cytoplasmic staining for CD68 and factor XIIIa (**Fig. 52-18B**). Fascin and CD4 may be expressed.[388] S100 is typically negative, although positivity has been reported in a significant proportion.[383,388] CD1a and langerin (CD207) are not expressed.

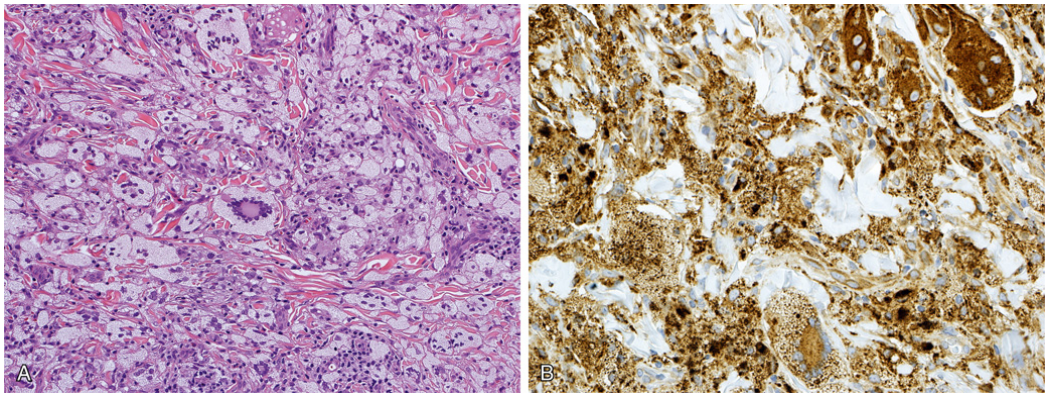

FIGURE 52-18 Juvenile xanthogranuloma.A, The lesion is composed of histiocyte with abundant foamy cytoplasm and Touton giant cells. There are occasional eosinophils. **B,** The lesional cells express CD68.

Genetics and Molecular Findings

The pathogenesis of JXG and related lesions has, until recently, been poorly understood. Studies using NGS have identified a role for

MAPK and PI3K pathway activation in cutaneous, extracutaneous, and disseminated types with the discovery of recurrent mutations in *MAP2K1, CSF1R, NRAS, KRAS, ARAF,*[275,373] and *MAPK1*,[400] and recurrent fusions involving *BRAF*,[376] *NTRK,* and *RET*.[275] A single case of JXG with a *MRC1::PDGFRB* fusion has been described.[401] The distinct subgroup of lesions with a JXG-like morphology that harbor ALK fusions are now classified as the separate entity of ALK-positive histiocytosis.[240,241,377]

The *BRAF* p.V600E mutation has rarely been described in a subgroup of intracranial JXG with a predilection for young males and aggressive/systemic disease.[402,403] These cases can show varying degrees of overlap with adult ECD: one patient had typical bone findings of ECD on imaging studies and was diagnosed as ECD; other cases have shown associated neurodegenerative changes in the absence of other features of ECD.[403] These findings raise the consideration as to whether intracranial JXG with *BRAF* p.V600E mutation could fall within an expanded spectrum of pediatric ECD, or whether this could represent a distinct subgroup of JXG.[403] The *BRAF* p.V600E mutation has also been found in cases of histiocytosis with a mixed LCH and JXG phenotype.[269]

Copy number analysis has indicated that genomic abnormalities are uncommon in solitary lesions of JXG.[404] JXG can also arise in the setting of neurofibromatosis with germline *NF1* mutations.[269]

Clinical Course and Prognosis

Cutaneous and solitary extracutaneous JXG typically follows a benign course with gradual regression of the lesions over months to years and a low rate of local recurrence if treated by excision.[383,384]

Lesions in adults tend to persist rather than spontaneously regress.[2] Systemic JXG, including forms with ocular and CNS involvement, may result in significant morbidity[394] and require resection or chemotherapy for treatment. Very rarely, the disease can be fatal.[384]

Association With Hematologic Malignancies

Lesions with the morphology and immunophenotype of JXG have been seen in association with hematologic malignancies in both adults and children, though particularly in adults, including in B-ALL,[405,406] large B-cell lymphoma,[406] ATLL,[407] MDS,[408] CLL,[409] MGUS,[409] and MPNs.[410] Some lesions in this setting may show atypical features, including nuclear pleomorphism and an increase in proliferation index.[411] A clonal relationship between the JXG and hematologic malignancy was shown in a case with preceding T-ALL.[412]

Differential Diagnosis

JXG with a spindled morphology may raise the consideration of other cutaneous lesions such as dermatofibroma or blue nevus. ECD is within the histologic differential diagnosis, and warrants particular consideration in adults and in cases with detectable *BRAF* p.V600E mutation. Rarely, JXG can involve the bones, and needs to be distinguished from LCH with reparative and reactive inflammatory changes.

ALK-Positive Histiocytosis

Definition

ALK-positive histiocytosis is a rare histiocytic neoplasm characterized by the immunohistochemical expression of ALK within

atypical histiocytes and associated with *ALK* fusions, particularly *KIF5B::ALK*.[377,413]

Synonyms and Related Terms

ALK-positive histiocytosis (ICC); ALK-positive histiocytosis (WHO 5th ed.); Not included (WHO Revised 4th ed); included within category of ECD (Revised Classification of the Histiocyte Society, 2016).

Background

ALK-positive histiocytosis was first described in 2008 by Chan et al.[414] in a case series of three infants who presented with massive hepatosplenomegaly, anemia, and thrombocytopenia with tissue infiltration by an atypical histiocytic population showing ALK immunoreactivity. A *TPM3::ALK* fusion was identified in one case. Since then, there have been sporadic case reports and small series of ALK-positive histiocytosis, showing that the clinical spectrum of the disorder is broader than first described and identifying the *KIF5B::ALK* fusion as a recurrent abnormality.[413] In the 2016 classification of the Histiocyte Society, the disease falls in the L group of histiocytic disorders within the spectrum of ECD.[2] Recent reports,[413,415] including a large case series,[377] have suggested that there is sufficient evidence for this to be recognized as a specific entity and it is now recognized as such in the ICC[240] and in the WHO 5th edition.[241]

Epidemiology

ALK-positive histiocytosis shows a female predilection and occurs over a wide age range (0–66 years),[377,413,416] but the majority of

cases occur in childhood (79% in the largest study to date with a median age of 3 years).[377] One case has been described in association with CLL/SLL with identical immunoglobulin heavy-chain gene (IGH) rearrangements in both neoplasms.[417]

Clinical Features

ALK-positive histiocytosis has a varied clinical presentation. In accordance with the original description, it may manifest in young infants as liver and hematologic involvement with hepatomegaly, splenomegaly, anemia, and thrombocytopenia.[377,413,414] Other patients may present with a multisystem disease involving liver, lungs, bone nervous system, or lymph nodes. The disease may also involve a single system, often the central and peripheral nervous system with neurologic symptoms, but may be localized to lung, bone, breast, gastrointestinal tract, and skin.[377,413,415,418]

Morphology

The morphology is variable, but cases show a xanthogranulomatous morphology with foamy histiocytes and Touton-type giant cells, or are cellular and monomorphic without lipidized histiocytes.[377] Histiocytes can also have a spindled or epithelioid morphology, and nuclei are often slightly indented (**Fig. 52-19A–B**). In rare cases, the histiocytes can express S100 and show emperipolesis, strongly resembling RDD.[377]

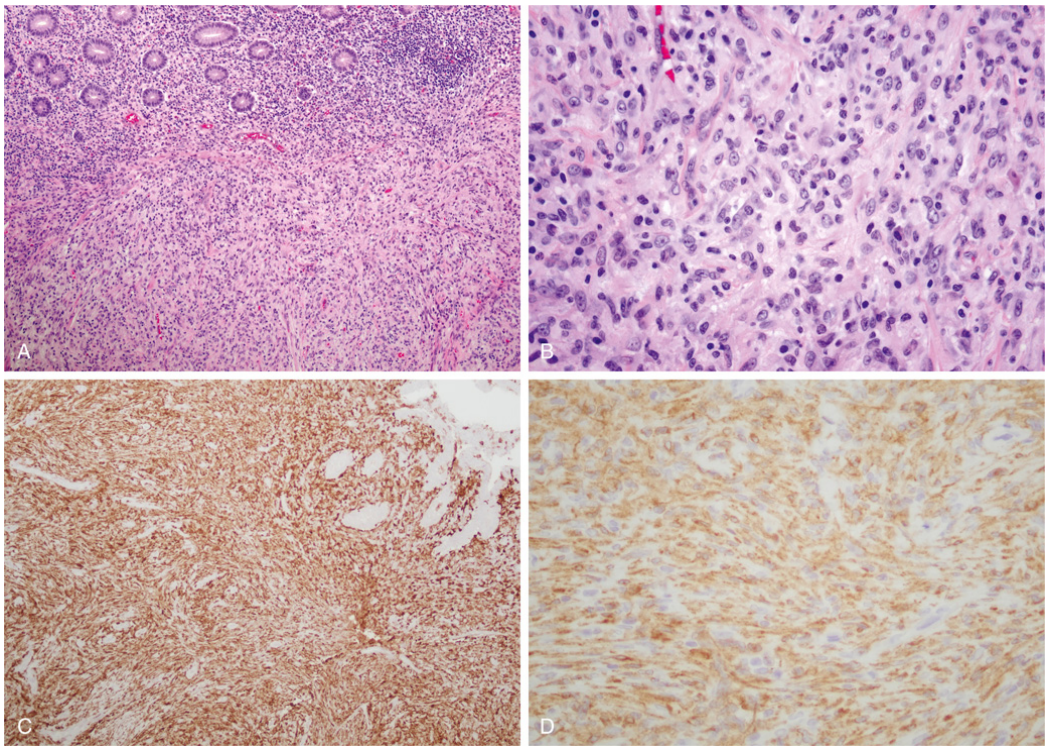

FIGURE 52-19 ALK-positive histiocytosis.A, An infiltrate with a spindled, histiocytoid morphology undermines the gastrointestinal tract mucosa. The cells have pale eosinophilic cytoplasm and oval to slightly indented nuclei **(B)** and express CD163 **(C)**. There is cytoplasmic positivity with ALK **(D)**.

The infiltrate may be focally subtle in involved liver biopsies and comprise only single cells or small aggregates in the sinusoids, though is more conspicuous in portal tracts. The histiocytes may be difficult to distinguish from hepatocytes, therefore ALK IHC may be required for identification.[413] Bone marrow involvement is typically focal and patchy,[377] though may be extensive.[413]

Immunophenotype

The tumor shows ALK immunoreactivity, usually with a cytoplasmic pattern with or without membranous staining; however, cases with exclusively dotlike Golgi positivity and cases with only focal weak staining are described. The pattern of ALK staining by IHC does not correlate with the underlying molecular alteration. The atypical cells express histiocytic markers CD163 and CD68, and are often positive for factor XIIIa (**Fig. 52-19C–D**). S100 and OCT2 are variably expressed, and cyclin D1 shows nuclear staining. CD1a is negative.[377,413]

Genetics and Molecular Findings

Most of the cases carry a recurrent fusion in *KIF5B::ALK,* usually with exon 24 of *KIF5B* fused to exon 20 of *ALK*.[377,413,415] Other ALK fusions have also been identified, including *COL1A2::ALK*,[413] *TRIM33::ALK*,[419] *CLTC::ALK, TPM3::ALK, TFG::ALK, EML4::ALK,* and *DCTN1::ALK*.[377,413]

If possible, the presence of an *ALK* rearrangement should be confirmed by molecular methods in order to confirm the diagnosis of ALK-positive histiocytosis. Cases with ALK staining but lacking *ALK* rearrangements may not benefit from ALK inhibition, and such cases may have other somatic activating alterations in the MAPK pathway.[377]

Clinical Course and Prognosis

The clinical course is diverse. Spontaneous resolution of disease can occur in infantile presentations, but progressive disease and death also occur. Although sustained complete responses have been seen with conventional chemotherapy in a few patients with multisystem

disease, ALK inhibition has been found to induce significant and durable responses.[377,413,420,421]

Differential Diagnosis

ALK-rearranged tumors with prominent intermixed histiocytic infiltrates pose a particular diagnostic pitfall. A recent study[377] described a group of atypical *ALK*-rearranged histiocyte-rich tumors, in which the ALK-positive cells were within a histiocyte-rich background and often had a similar morphology to the atypical cells in ALK-positive histiocytosis; however, they did not express lineage-specific markers. Other *ALK*-rearranged entities, such as inflammatory myofibroblastic tumor and epithelioid fibrous histiocytoma, require exclusion.

ALK-positive histiocytosis and ECD may have a similar morphology and ALK-positive histiocytosis may present with bone involvement in a similar fashion to ECD. However, ECD patients are typically older than those with ALK-positive histiocytosis, and other characteristic imaging findings of ECD are generally absent. Furthermore, ALK immunoreactivity and *ALK* rearrangement can be demonstrated in ALK-positive histiocytosis but not in ECD, which may harbor the *BRAF* p.V600E or other MAPK pathway mutations. As noted previously, some cases may also show emperipolesis and resemble RDD; however, positivity for ALK will aid in its distinction from this entity.[377]

Rosai-Dorfman Disease

Definition

RDD, also known as Destombes disease[422] or sinus histiocytosis with massive lymphadenopathy,[423] is a rare non-Langerhans histiocytic disorder characterized by tissue infiltration of S100-positive, CD68-positive, and CD1a-negative macrophages typically engulfing living cells in their cytoplasm, a phenomenon termed *emperipolesis*. In the updated Histiocyte Society classification of histiocytoses,[2] RDD is categorized in the R group, which includes nodal classical RDD, extranodal RDD, immune-disease or neoplasia-associated RDD, and genetic-related RDD, while the exclusively cutaneous RDD is classified in the C group. Classical RDD typically occurs in young individuals, presenting with massive bilateral enlargement of cervical lymph nodes, often accompanied by fever and weight loss.[422,423] In most cases, RDD has an indolent course with spontaneous remission and excellent prognosis. Persistent disease is rare, and few patients have poor outcomes. Originally considered a reactive process, the occurrence of clonal mutations involving the MAPK pathway supports a neoplastic origin in at least a fraction of cases, and consequently it has been included in the *histiocytic and dendritic cell neoplasms* category in both the ICC of Mature Lymphoid Neoplasms[240] and in the WHO 5th edition Classification of Haematolymphoid Tumours.[241]

Synonyms and Related Terms

Rosai-Dorfman-Destombes disease (ICC); Rosai-Dorfman Disease (WHO 5th ed.).

Epidemiology

RDD can occur at any age but is most common in the 1st and 2nd decades of life (median age: 20.6 years), with a slight male

preponderance[424] and predilection of African ancestry.[423] The cutaneous form is more frequent in women of White and Asian origin with a median age at onset of 43.5 years.[425,426]

Etiology

For a long time after its first description, RDD has been considered a benign reactive condition,[427] composed of macrophages activated by macrophage colony-stimulating factor.[428] A relationship with viral infections has been proposed without definite evidence. IgG4-positive plasma cells can be elevated in RDD, even reaching the cutoff values of IgG4-related diseases; however, the significance of this finding remains unclear and a definite relationship with IgG4-related sclerosing diseases has not been established.[429,430] Nevertheless, it is recommended that all cases of RDD be evaluated for IgG4-positive plasma cells.[2]

Recent data reporting clonal somatic mutations in up to 33% of cases of RDD indicate that at least a fraction of RDD represent a neoplastic process.[373,424,431-433]

Associated Diseases

Two inherited conditions predispose to RDD: the "histiocytosis-lymphadenopathy plus syndrome" associated with germline biallelic mutations of the *SLC29A3* gene encoding for the equilibrative nucleoside transporter 3,[434,435] and ALPS type I, caused by mutations in the FAS gene *TNFRSF*.[436] The "histiocytosis-lymphadenopathy plus syndrome" encompasses H syndrome, Faisalabad histiocytosis, familial RDD, and pigmented hypertrichosis with insulin-dependent diabetes mellitus. These disorders have overlapping signs and symptoms[437,438] and in 20% of cases are

characterized by accumulation of histiocytes with morphologic and phenotypical features of RDD, involving lymph nodes, skin, and nasal and oral mucosa.[434]

RDD-like lesions have been found to occur in 18 out of 44 (41%) lymph nodes of patients with ALPS type I and were associated with male predominance and early age of onset, without effect on the clinical course.[436] Notably, in 2 out of 18 cases, the histiocytic infiltrates were abundant and confluent, with distortion of the lymph node architecture, while in the remaining cases, the RDD-like lesions consisted of multifocal or isolated collections of S100-positive histiocytes with emperipolesis.

In 10% of cases, RDD occurs in patients with an immunologic disease, including systemic lupus erythematosus, idiopathic juvenile arthritis, and autoimmune hemolytic anemia.[424,439,440]

RDD has been reported in patients with myelodysplasia, acute leukemia, LCH, and ECD.[441,442] RDD and ECD can occur at diagnosis involving different sites, or the RDD lesions can develop later in time, with a peculiar predilection for the testis in elderly males.[443]

RDD-like lesions have been observed in patients with Hodgkin and non-Hodgkin lymphomas. In a few cases, the two diseases occurred in different sites at different times, while more frequently the RDD lesions were found in the same lymph node and mostly consisted of small collections of histiocytes showing emperipolesis.[167,444-447]

Clinical Features

RDD mostly involves single or multiple lymph nodes, which in 25% to 43% of cases are associated with at least one extranodal lesion,

sometimes representing the initial manifestation of the disease.[439,440] In adult patients, however, skin involvement can be prevalent.[425,426,448] In 23% of cases, RDD occurs only in extranodal sites, especially skin, CNS, nasal cavity, and paranasal sinuses.[440,449] In 19% of cases, RDD has a multisystem spread.[440]

Patients with classical RDD are frequently young individuals (average age at onset of 20.6 years) with painless, massive bilateral cervical lymphadenopathy, sometimes accompanied by low-grade fever and weight loss.[422,423] Neutrophilic leukocytosis, mild normochromic normocytic anemia, polyclonal gammopathy, and elevated erythrocyte sedimentation rate can be observed in some cases.[440,448,450] Inguinal, axillary, and mediastinal lymph nodes are more rarely involved, while retroperitoneal adenopathy is rare.

The extranodal sites more frequently involved include skin (10%, up to 52%),[448] nasal cavity and paranasal sinuses (11%), orbital tissues (11%), bones (5%–10%), CNS (5%), and kidneys (4%).[424,430] More rarely, RDD localizes in the oral cavity and salivary glands, larynx, pharynx, thyroid gland, lungs, thymus, liver, spleen, pancreas, breast, testis, and the gastrointestinal tract. Bone marrow is exceptionally involved by RDD.[424,440,448]

Cutaneous RDD can occur at any site, with prevalence of the extremities (54%) and trunk (47%), rarely with a generalized distribution; the lesions consist of reddish-brown papules, nodules, or large plaques measuring up to 30 cm, and can be asymptomatic or associated with tenderness or pruritus.[449,451] Sinonasal RDD causes nasal obstruction, epistaxis, or facial asymmetry, while oral cavity involvement manifests as soft and hard palate nodules, mucosal thickening, or tonsillitis.[440,452] Ophthalmic lesions mostly consist of

expansive masses, uveitis, or compressive optic neuropathy.[424] RDD affecting bones is typically associated with nodal disease[440] and it mainly involves the metaphysis or diaphysis as osteolytic or mixed lytic/sclerotic lesions, causing pain and rarely pathologic fractures; it usually has a good prognosis with spontaneous involution of the lesions.[453] CNS RDD occurs as intracranial (75%) or spinal lesions (25%) associated with highly variable symptoms. The disease can be rapidly progressive and fatal, but patients eligible for surgical resection can have a favorable outcome.[454,455] Kidney involvement by RDD can manifest as a mass or diffuse infiltration, associated with pain, hematuria, renal failure, hypercalcemia, or nephrotic syndrome caused by amyloidosis or renal vein thrombosis, resulting in a mortality rate of 40%.[424,440]

Morphology

Lymph nodes involved by RDD are characterized by capsular sclerosis and follicular hyperplasia with significant dilatation of the sinuses by an infiltrate of large histiocytes, and accumulation of plasma cells in the medullary cords and intersinusoidal areas, the latter two findings resulting in a characteristic light and dark pattern of the parenchyma (**Fig. 52-20A–B**). In more advanced cases, the architecture is effaced by fibrosis and by a diffuse infiltrate of histiocytes, admixed with lymphocytes and plasma cells.

The histiocytes in RDD have an abundant pale eosinophilic cytoplasm; single or multiple large hypochromatic nuclei with a delicate nuclear membrane; and eosinophilic, often prominent, nucleoli (**Fig. 52-20C**). Emperipolesis consists of the occurrence of intact cells (lymphocytes, small macrophages, neutrophils, or plasma

cells) within cytoplasmic vacuoles of the histiocytes, and it is highlighted on sections immunostained for S100 (**Fig. 52-21B**); emperipolesis is easily detectable on fine-needle aspiration cytologic specimens (**Fig. 52-20D**).

RDD identification in extranodal sites is sometimes difficult because the hallmark histiocytes can occur in small foci or as scattered cells and emperipolesis is less obvious; moreover, fibrosis can be prominent, plasma cells can be less numerous, and neutrophils are sometimes abundant, even forming microabscesses.[424,430] IHC is often necessary to identify the RDD cells and the diagnosis can require multiple biopsies (**Fig. 52-22A–C**).[448]

Immunophenotype

RDD histiocytes express multiple macrophage markers such as CD11c, CD14, CD68, CD163, and lysozyme, and are typically positive for the S100 protein[166,424,430,456,457] but negative for the dendritic cell markers CD1a, CD207, and ZBTB46.[333,458] In addition, they show diffuse expression of cyclin D1 and OCT2 and lack HLA-DR, in contrast to other histiocytic-derived tumors (**Fig. 52-21A–C**).[333,426,459]

Positivity for phosphorylated extracellular signal-regulated kinase (p-ERK) has been related to mutations activating the MAPK pathway[426,432,459] but found also in nonmutated cases.[460]

Genetics and Molecular Findings

Recurrent mutations affecting the mitogen-activated protein kinase/extracellular signal-regulated kinase (MAPK/ERK) pathway have been found in about one-third of RDD cases.[424] Mutations of

KRAS[424,426,432,461,462] and *MAP2K1*[275,373,426,431,432,462] are the most frequently reported and are mutually exclusive.[432] Their occurrence is associated with younger age, head and neck region involvement, and multifocal presentation, but unrelated with the clinical outcome.[432] Other less-frequent mutations identified in RDD involve *ARAF, CSF1R, NF1, PTPN11, SMARCA4, PTEN,* and *NRAS*,[275,373,424,426,462] the latter especially found in the purely cutaneous forms of RDD.[463]

Notably, *BRAF* mutations, commonly encountered in other histiocytic disorders such as ECD and LCH, have been detected in cases of RDD associated with these diseases,[441,442] but only exceptionally in isolated RDD.[464] Notably, in the series of RDD cases associated with ECD, none of the RDD cases had *BRAF* mutations, the majority (9/12) having mutations of *MAP2K1,* which was identified also in the Erdheim-Chester histiocytes in only two cases.[443]

Clinical Course and Prognosis

Most cases with nodal and cutaneous disease have an indolent and often self-limited course with an excellent prognosis. Other patients experience alternating periods of remission and reactivation that may last years. In the series of Foucar et al.,[440] 17 out of 238 (7%) patients died because of disease-related complications, infections, or amyloidosis. In another study, disease-dependent death was reported in 10 out of 80 patients (12%).[465] Negative prognostic factors include extensive nodal disease, and multifocal and extranodal RDD, particularly involving the kidney, the liver, or the lower respiratory tract.[424,440] Patients with CNS involvement not

eligible for surgical resection have an unfavorable prognosis.[454,455] Whether the occurrence of clonal mutations influence the clinical behavior is still controversial.[432,462]

A uniform treatment approach has not been defined for RDD, and it is generally tailored to the individual clinical circumstances, and particularly to the number and site of lesions, recurrences, presence of systemic symptoms, and life-threatening disease.[424,448,466] Thus, treatment can vary from a watch-and-wait approach to surgical resection of the primary and eventually relapsing localized disease, corticosteroids, radiation therapy, cladribine-based chemotherapy for multifocal disease, and immunomodulatory strategies (e.g., lenalidomide, thalidomide, sirolimus, or methotrexate).[424,448,466] Significant responses to MEK inhibitors have been reported in cases with advanced and therapy refractory disease, independently from the occurrence of MAPK-activating mutations.[461,467-470]

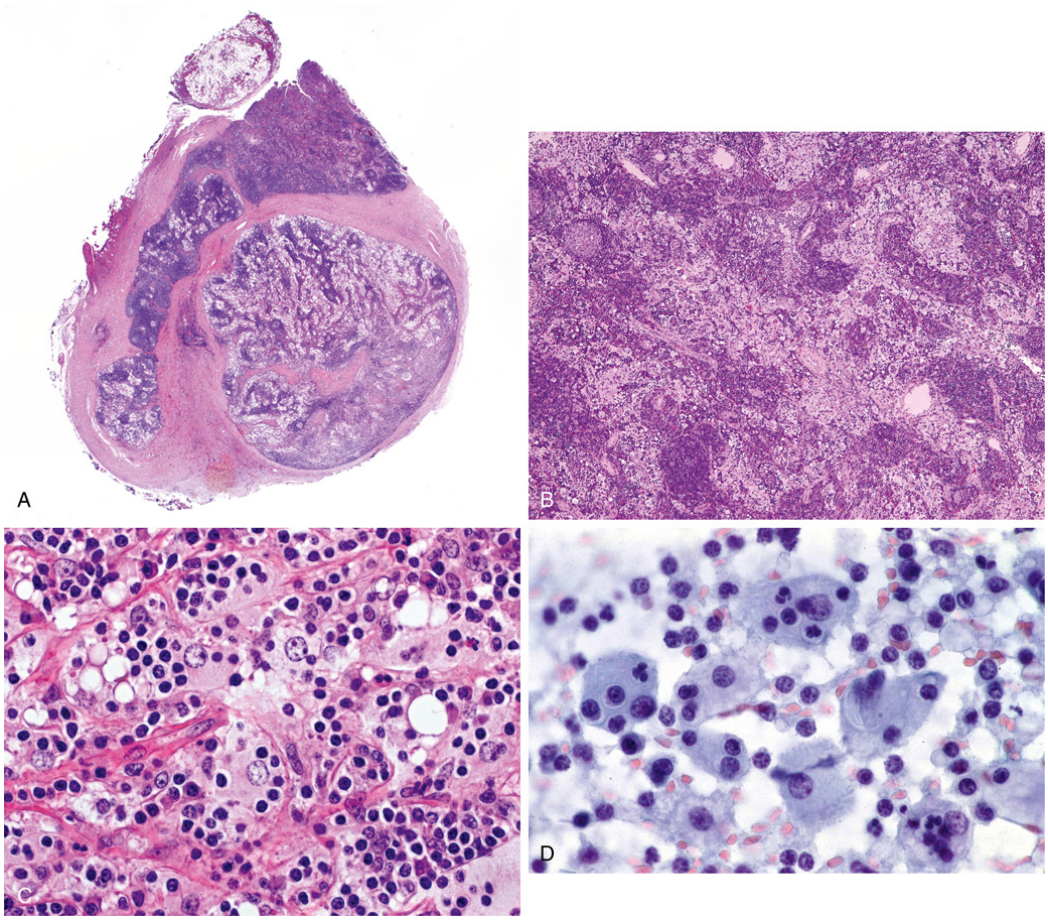

FIGURE 52-20 **A–B,** Rosai-Dorfman disease involving a lymph node: note the sclerotic capsule with septa and the parenchyma showing pale and dark zones, the former corresponding to dilated sinuses containing histiocytes, the latter to lymphocyte and plasma cell rich areas. **C,** The morphologic details of the histiocytes: large cells with pale eosinophilic cytoplasm engulfed by nucleated cells, some of which are surrounded by a clear halo; the nuclei of the histiocytes contain a prominent nucleolus. **D,** Fine-needle cytology showing marked emperipolesis.

Differential Diagnosis

In lymph nodes, marked sinusoidal involvement by S100-positive histiocyte-looking cells occurs in LCH,[333] but the distinctive cell morphology and phenotype of Langerhans cells, together with the presence of eosinophils and lack of significant plasmacytosis and emperipolesis easily allow the distinction from RDD. Hemophagocytic syndromes, especially the familial form occurring in early life, can mimic RDD because of the prominent sinus collection of phagocytizing macrophages. These macrophages, however, engulf many erythrocytes together with nucleated cells and are negative for S100. Moreover, these syndromes are characterized by disseminated disease and an aggressive clinical course, which is quite uncommon in most RDD cases.

Although the prominent nucleoli of the histiocytes in RDD can give them an atypical appearance, the absence of mitotic activity is useful in ruling out malignancy, such as S100-positive melanomas and HS.[333]

Multiple or isolated RDD-like lesions may occur in lymph nodes involved by Hodgkin and non-Hodgkin lymphomas[167,444-447] and in lymph nodes from patients with ALPS.[436] These aggregates are distributed at the periphery of tumor nodules (**Fig. 52-23A–B**) or at the periphery of reactive follicles and in the expanded paracortex, admixed with numerous S100-positive interdigitating dendritic cells; sinuses are spared or minimally involved. Emperipolesis is generally focal and the S100 macrophages are negative for CD163.[447] These lesions are generally an incidental finding and not associated with overt RDD. According to the consensus diagnostic

recommendations, a RDD diagnosis should not be rendered when these foci involve less than 10% of the whole node.[424]

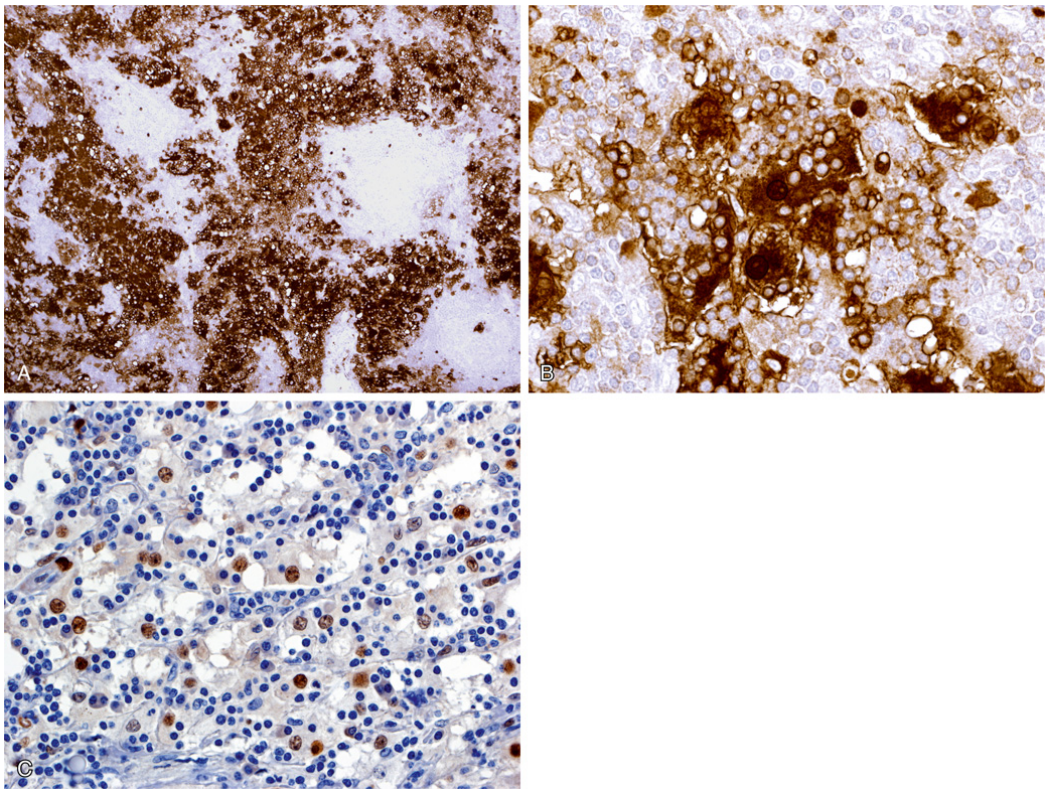

FIGURE 52-21 Massive sinusoidal involvement by the S100-positive histiocytes **(A)**, which contain numerous lymphoid cells in their cytoplasm **(B)**; note the positivity for S100 also of the histiocyte nuclei, in contrast to that of the phagocytosed cells, which are negative. The nuclei of the histiocytes are strongly positive for cyclin D1 **(C)**.

Nevertheless, the pathogenesis of these focal RDD-like lesions is intriguing. It has been suggested that they may result from abnormal monocyte recruitment and activation by cytokines occurring in

lymphomas, or by the dysregulated immune environment taking place in ALPS.[436] The occurrence of numerous S100-positive interdigitating dendritic cells associated with these foci together with a morphologic spectrum ranging from S100-positive dendritic cells to S100-positive histiocytes with emperipolesis (**Fig. 52-23B**) suggested a possible derivation from activated interdigitating dendritic cells.[167] Notably, despite none of these cases showing mutations associated with classical RDD, the histiocytes are positive for cyclin D1 and p-ERK, suggesting that these focal RDD-like lesions might be the result of an autocrine or paracrine loop driving MAPK/ERK signaling.[447]

The distinction of RDD from other histiocytic diseases occurring in the skin and bones, such as ECD and JXG, can be challenging, because macrophages can focally express S100 and show emperipolesis. However, foamy cells and Touton-like multinucleated cells are very uncommon in RDD; moreover, OCT2 is generally negative in ECD.[459] In cases not easily resolved on the histologic and phenotypic basis, molecular evaluation and close clinical correlation is recommended.[424]

Macrophages occurring in ALK-positive histiocytosis can express S100 and show emperipolesis, strongly resembling RDD[167,333,414,471]; this advises to include stain for ALK in cases showing RDD features, especially when they occur in very young individuals with multifocal disease or in adults with CNS, skin, or breast lesions.

Combined (Mixed) Histiocytoses

Studies looking at the co-occurrence of LCH and non-LCH suggest that this phenomenon is a not infrequent finding. It most commonly occurs as a combination of LCH and ECD and mixed histiocytosis has been reported as accounting for up to 19% of the ECD cohort in one center.[380] The patients present with similar clinical findings to isolated LCH or ECD; however, at an age (~40 years) that is slightly older than that at typical presentation with LCH and younger than that with ECD. Patients are almost always diagnosed with LCH prior to or concurrent with ECD and there is an association with *BRAF* p.V600E.[380] Interestingly, a patient with LCH, ECD, and papillary thyroid carcinoma, all harboring *BRAF* p.V600E mutation, has been described.[472] LCH co-occurring with RDD and JXG has also been reported; however, the molecular relationship between these has mostly not been explored[473,474]; cases of histiocytosis showing a mixed LCH and JXG phenotype with *BRAF* p.V600E mutations have been described.[269]

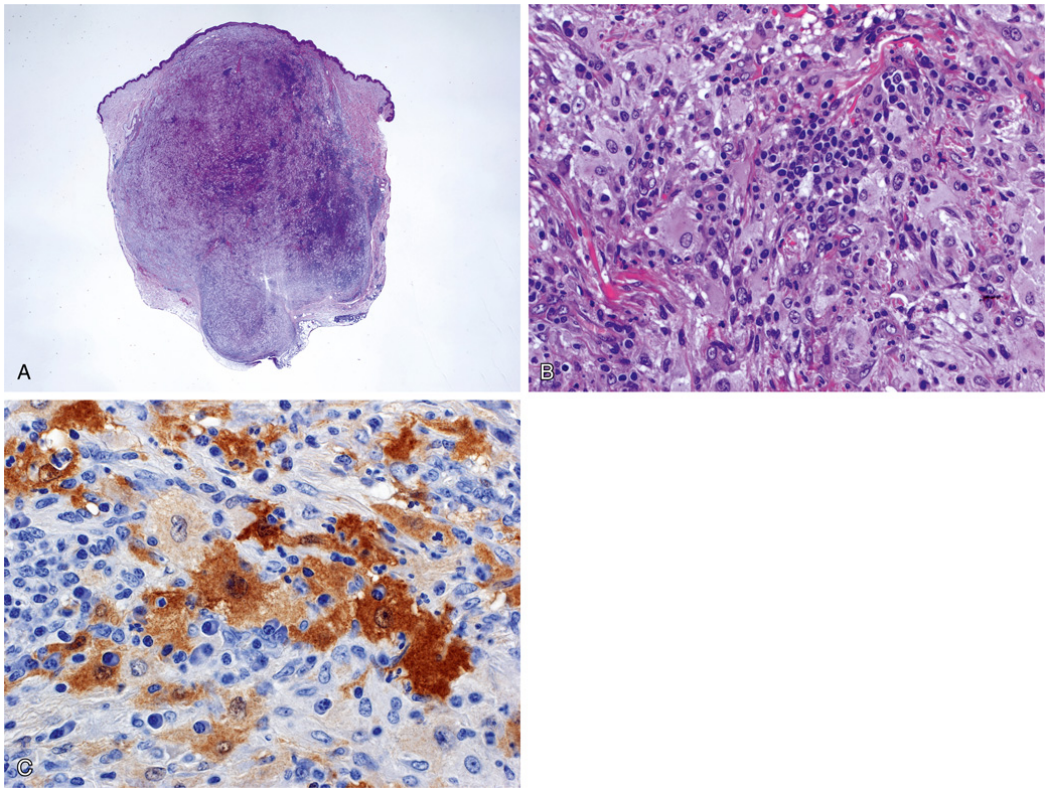

FIGURE 52-22 **A,** Cutaneous Rosai-Dorfman disease showing a large nodule involving the dermis and extending to the subcutaneous fat. The large histiocytes are scattered among inflammatory cells and emperipolesis is less obvious **(B)**, but easily recognizable on the S100-protein immunostained section **(C)**.

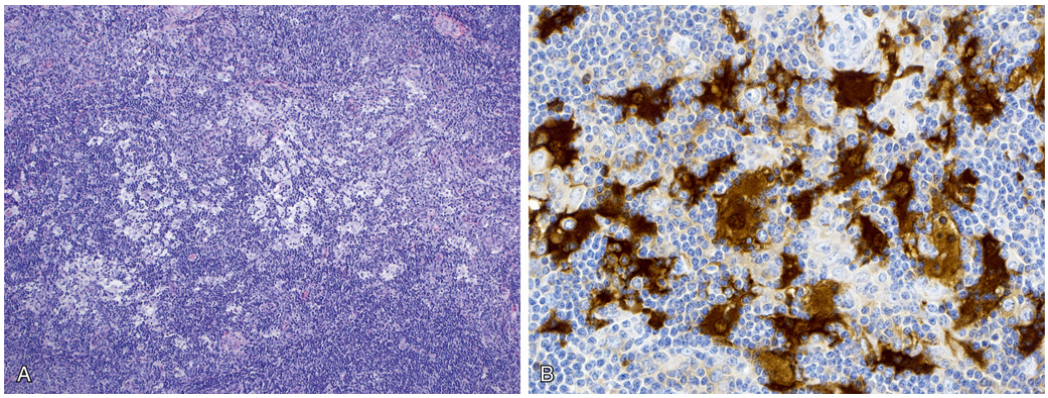

FIGURE 52-23 Small areas of Rosai-Dorfman disease–like histiocytes in a case of lymphocyte-predominant nodular Hodgkin lymphoma **(A)**; these cells are positive for S100, show emperipolesis, and many of them display a dendritic morphology **(B)**.

Biopsies from a subset of ECD patients with *MAP2K1* mutations may show histologic overlap with RDD and a predilection for testicular involvement.[443,475]

Malignant Histiocytic/Dendritic Cell Neoplasms

Malignant histiocytic/dendritic cell (H/DC) neoplasms are distinguished from other histiocytoses by a combination of atypical histologic features, including marked cellular pleomorphism and an increased mitotic rate, and a tendency to demonstrate aggressive clinical behavior.[2] Diagnosis and classification may be challenging as the minimum histologic criteria required for a diagnosis of malignancy are not established, and thresholds for antibody positivity when subtyping by IHC are not defined.

Evaluation of an IHC panel is central to final classification as HS, LCS, or interdigitating dendritic cell sarcoma (IDCS), although in the

setting of immunophenotypic heterogeneity precise classification may be subjective and rely on the identification of a dominant component within the tumor.[333] The nomenclature of the ICC and WHO classifications does not distinguish a separate malignant tumor subtype with immunophenotypic features of IDCH; however, in the revised 2016 classification from the Histiocyte Society, malignant histiocytosis can be classified as indeterminate cell subtype, separate to the category of indeterminate cell histiocytosis.[2]

Malignant H/DC neoplasms are referred to as either primary (sporadic or occurring de novo), or as secondary (in which there is a clonally related associated malignancy). This is most often an associated lymphoid malignancy, with associated FL,[476,477] chronic lymphocytic leukemia/lymphoma,[478] T-lymphoblastic leukemia, B-lymphoblastic leukemia,[479] hairy cell leukemia,[480] and mantle cell lymphoma[481] described, among others. It is generally postulated that the secondary H/DC neoplasm arises through a poorly understood process termed *transdifferentiation*, whereby a mature cell of lymphoid lineage is converted to a mature myeloid lineage cell. In support of this theory, it has been shown in vitro that enforced expression of C/EBPα in B cells results in the downregulation of PAX5 and the activation of myeloid/macrophage differentiation programs.[482] The clonal relationship between the lymphoid malignancy and H/DC neoplasm has been well established in multiple reports through the demonstration of shared IG or TR rearrangements or shared cytogenetic abnormalities, such as the presence of the *IGH*::*BCL2*[476] rearrangements in both components. However, more recent comparative studies using NGS have yielded further insight into the nature of this clonal relationship with the

discovery that the lymphoid and H/DC components harbor both shared and unique mutations, thus providing evidence in some cases for divergent evolution of each component from a common lymphoid precursor cell, and highlighting the acquisition of MAPK pathway–activating mutations as important in the pathogenesis of the H/DC neoplasm.[352,483-485]

Finally, the discovery of frequent activating alterations in the MAPK pathway has offered the potential of treatment with targeted therapeutic agents such as BRAF or MEK inhibitors in these aggressive neoplasms.[486,487]

Histiocytic Sarcoma

Definition

Histiocytic sarcoma (HS) is a malignant tumor with morphologic and immunophenotypic features of mature tissue histiocytes. It may arise de novo (primary HS) or clonally related to another hematologic malignancy, in particular low-grade B-cell lymphoma and lymphoblastic lymphoma (secondary HS). Recent studies have shown that MAPK pathway activation plays an important role in the pathogenesis of this disease.[488,489]

Synonyms and Related Terms

Histiocytic sarcoma (ICC) Histiocytic sarcoma (WHO 5th ed.); Histiocytic sarcoma (WHO Revised 4th ed.); Primary/secondary malignant histiocytosis, histiocytic subtype (Revised Classification of the Histiocyte Society, 2016).

Epidemiology

HS is rare. With advancements in IHC, many cases that were historically diagnosed as true histiocytic lymphoma or malignant histiocytosis have been reclassified as other forms of neoplasia, particularly diffuse large B-cell lymphoma (DLBCL) and anaplastic large cell lymphoma.[490-492]

In a study using data from the Surveillance, Epidemiology, and End Results (SEER) Program database (2000–2014) and including only adult patients, the overall incidence was calculated at 0.17 per 1000,000 individuals and the disease was more common in males than in females,[493] although notably some recent studies have shown a female predominance.[488,489] HS has a wide age range and occurs in both children and adults.[488,489,494]

Secondary HS accounts for ~20% of cases in some of the larger cohorts[489,494] and has been described in association with FL,[476] chronic lymphocytic leukemia,[478] marginal zone lymphoma,[495,496] hairy cell leukemia,[480] Burkitt lymphoma,[497] DLBCL,[494] mantle cell lymphoma,[481] B-lymphoblastic leukemia/lymphoma,[479,498] and T-lymphoblastic leukemia/lymphoma.[411,499] Rare cases have occurred in association with mediastinal germ cell tumors[500,501] and myeloid disorders including CMML,[351] MDS,[500] and biphenotypic/bilineal (B/myeloid) leukemia.[502] A case has also been reported in a patient with ALPS and RDD.[503]

Clinical Features

HS most commonly involves extranodal sites including the gastrointestinal tract, CNS, skin, soft tissue, spleen, bone,[504] and lymph nodes.[505] Patients present with symptoms related to the site of involvement including hepatosplenomegaly, lymphadenopathy,

painful or painless masses, intestinal obstruction, or pancytopenia.[504,506] Systemic symptoms including fever, fatigue, and weight loss may also be present.[507]

Morphology

The atypical cells of HS have a varied appearance, but are usually medium-to-large in size with abundant eosinophilic cytoplasm. Some cells may have a foamy or xanthomatous appearance and cytoplasmic vacuolization may be present. There is often pronounced cytologic atypia with pleomorphic, bizarre, or folded nuclei (**Fig. 52-24A–C**). Multinucleated giant cells can be present and mitotic figures may be numerous with atypical forms (**Fig. 52-24D**). Hemophagocytosis by the neoplastic cells may be present.[164] The tumor cells can form diffuse sheets, and sarcomatoid areas with a storiform growth pattern have been described in some cases.[505] A prominent stromal inflammatory infiltrate is frequently present, most often composed of neutrophils or lymphocytes, but eosinophils or plasma cells may be present. There may be areas of necrosis. Sinusoidal involvement is frequently a feature in lymph node, bone marrow, and spleen biopsies.[504]

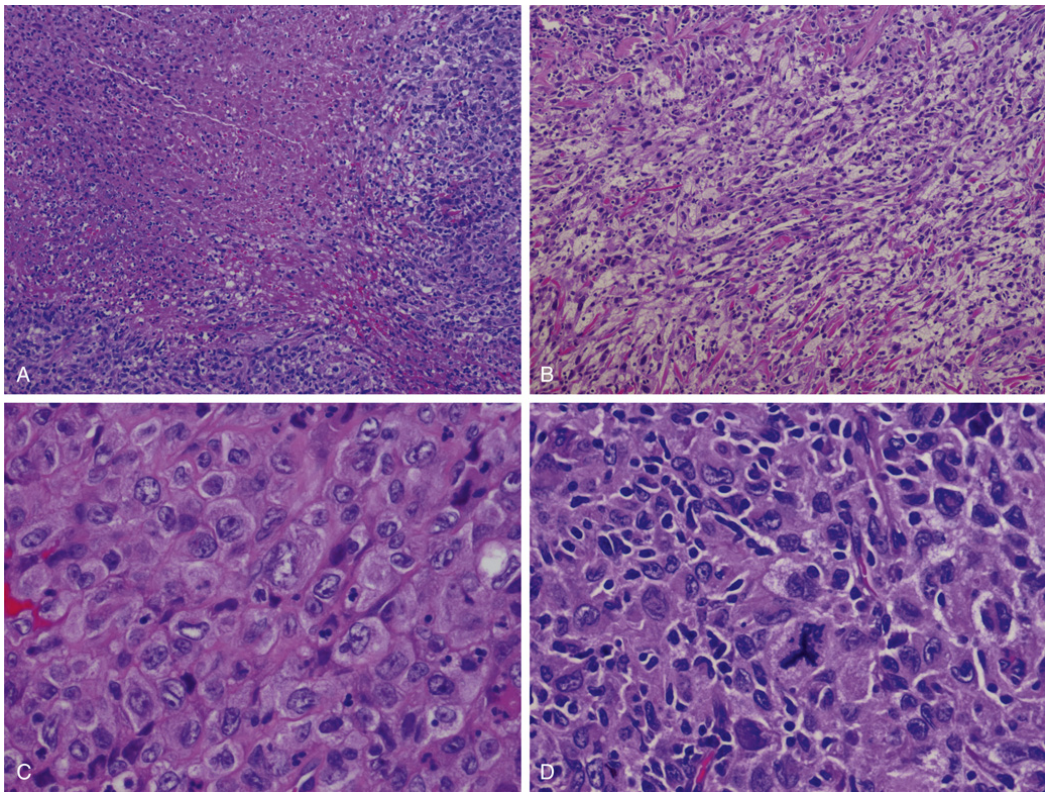

FIGURE 52-24 Histiocytic sarcoma.A, The atypical cells surround foci of necrosis. **B,** There are sheets of atypical, pleomorphic cells, some of which have foamy or xanthomatous cytoplasmic appearances. **C–D,** The neoplastic cells show marked cytologic atypia with pleomorphic, bizarre, or folded nuclei and atypical mitoses are present.

As HS may occur in association with a second hematologic malignancy, any lymphoid tissue in a biopsy should be carefully scrutinized to exclude a component of low-grade lymphoma.

Immunophenotype

The diagnosis of HS rests on the demonstration of immunophenotypic evidence of histiocytic derivation in tandem with the exclusion of tumors of other cell lineages such as carcinoma, melanoma, B and T cell lymphoma, anaplastic large cell lymphoma, and monocytic leukemia/myeloid sarcoma.

In general, there is expression of at least two histiocytic markers out of CD68, CD163, CD4, and lysozyme.[2] CD163 appears the more specific antibody for monocyte/macrophage lineage[508] as CD68 specificity depends on the antibody clone used. KP1 in particular is expressed in multiple tumor types.[509] HS usually shows significant expression of multiple histiocytic markers. CD14 and CD11c may also be positive, and variable S100 expression is not uncommon.[506] HS is negative for markers of Langerhans cell lineage (CD1a and Langerin [CD207]), FDCs (CD21, CD23, and CD35), B cells (PAX5, CD20), T cells (CD3), CD30, and myeloperoxidase. PD-L1 expression has been found in a proportion of cases, raising the possibility of potential therapeutic targeting using immune checkpoint inhibitors.[510]

Genetics and Molecular Findings

Evidence implicating activating mutations of the MAPK pathway in the pathogenesis of HS began to emerge around 2014.[511] Since then, multiple studies have described activating alterations in MAPK pathway genes in both primary and secondary cases of the disease, including mutations in *BRAF* (both p.V600E and non-p.V600E mutations), *MAP2K1, KRAS, NRAS, PTPN11, NF1,* and *CBL*.[352,488,489,494] *BRAF* fusions are also known to occur with diverse gene partners[488,494] and a *TPM3::NTRK1* fusion has been identified.[489]

Co-occurring MAPK pathway mutations are not uncommon and have been described in both primary and secondary HS cases. These most often involve a noncanonical *BRAF* mutation in combination with a *KRAS* mutation,[489,494,512] or the presence of concurrent *MAP2K1* mutations,[488,489,494] but other co-occurring mutations such as in *NF1* and *PTPN11*,[488] *KRAS* mutations co-occurring with *MAP2K1, RAF1* or *CBL* mutations,[494] and *BRAF* mutations co-occurring with *NF1, PTPN11, NRAS, RAF1,* or *HRAS* mutations[489,494,513,514] have been described. In the case with both *HRAS* and *BRAF* mutations, the *BRAF* p.F959L mutation was shown to have intermediate signaling activity, requiring cooperation with mutated *HRAS* for maximal oncogenic activity.[514]

Copy number losses in *CDKN2A* occur relatively often in HS.[352,488,489,494] Alterations in TP53, and mutations and alterations in the AKT/PI3K pathway, including mutations in *PTEN*[488,489,494] and *PI3KCA*[489] or amplification of *PIK3CA,*[494] are less frequently present. A subset of cases also harbors mutations in *SETD2;* in a single study this was associated with mutations in *NF1, PTPN11,* and gastrointestinal tract involvement.[488]

Multiple studies of secondary HS have shown a clonal relationship between the HS and the associated lymphoid malignancy through the identification of identical IG or TR rearrangements in the lymphoid and histiocytic components,[478,479,515-517] the presence of shared cytogenetic alterations such as *IGH*::*BCL2* rearrangement in cases associated with FL,[476] *IGH*::*CCND1* rearrangement in cases associated with mantle cell lymphoma,[481,518] or other shared genetic alterations, such as *CDKN2A* deletion or *BRAF* p.V600E mutation.[411,480]

More recently, comparative NGS studies have confirmed this shared clonal origin and provided further insight into the evolution of these neoplasms, particularly those associated with FL. In addition to a shared *IGH*::*BCL2* translocation and clonal IG rearrangement, NGS studies on two cases with paired FL and HS samples[352,485] have shown that both FL and HS components shared mutations in genes that are implicated in the pathogenesis of FL (*CREBBP* or *KMT2D*), but there was evidence of clonal divergence, characterized by acquisition of an activating mutation in the MAPK pathway in the HS component (*MAP2K1* or *KRAS*), and also by the presence of other mutations and copy number alterations that were unique to both FL and HS components.

Similarly, cases of FL-associated HS for which matched FL samples were not available for comparison were shown to harbor activating mutations in genes of the MAPK pathway, as well as mutations in *CREBBP, KMT2D,* or both.[352,494] Taken together with the evidence of an aberrant somatic hypermutation signature,[489] or of somatic hypermutation[495] in analyzed cases of B-cell lymphoma–associated HS, this suggests that cases of secondary HS in this context originate from a late-stage common precursor B-cell.

Intriguingly, some cases of primary HS without a known history of B-cell lymphoma have been shown to harbor IG gene rearrangements, *IGH*::*BCL2* rearrangements, or mutations in genes associated with B-cell lymphoma, suggesting that a proportion of apparently sporadic/primary HS may also have a B-cell origin or that an occult or subclinical B-cell lymphoma may be present.[519] Rarely, the diagnosis of HS may precede the diagnosis of the associated B-cell lymphoma.[520]

Although NGS studies have greatly added to the understanding of the evolution of these tumors, complexities remain. MAPK pathway mutations have not been identified in all cases,[496] and limited studies of HS associated with B-ALL and T-ALL with available comparative samples have shown shared alterations, including IG or TR rearrangements, but also shared MAPK mutations in some cases,[352,499] indicating that the mechanisms and genetic events involved in transdifferentiation are likely diverse.

There are rare cases of HS associated with mediastinal germ cell tumor, most without molecular data, but a clonal relationship has been demonstrated in some instances, such as shared isochromosome 12p. Shared identical *TP53* and *BCOR* mutations were shown in a case of mediastinal germ cell tumor associated with MDS and subsequent HS.[500] A further report has shown clonal relatedness with evidence of a common precursor with *TP53* and *PIK3CD* mutations giving rise to GCT, CMML, HS, and AML. The GCT and AML evolved from a daughter precursor with 1q and 21q gain, and the CMML and HS evolved from a separate daughter precursor, with the HS acquiring an additional *NRAS* mutation.[501]

Clinical Course and Prognosis

HS has a poor prognosis with a median overall survival of 6 months.[493] Owing to its rarity, there are no established standard-of-care treatment regimens, and most cases with multisite disease have been treated by lymphoma chemotherapy regimens such as ifosfamide, carboplatin, and etoposide (ICE) or cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP). Surgery and

radiotherapy have been used in the management of localized disease, or as part of a multimodal approach.[521]

More recently, case reports have detailed variable responses to novel, targeted therapeutic agents. BRAF and MEK inhibitors have been used in the treatment of cases with *BRAF* p.V600E and MAPK pathway mutations. While some cases have shown a good response to therapy, including to complete or near complete remission,[486,522] others have shown a good response but of limited duration.[523] Molecular evolution has been observed in a case after MAPK pathway inhibitor therapy, with loss of the *BRAF* p.V600E mutation and an *MTOR* mutation with an increasing allele frequency that was subsequently targeted with temsirolimus.[524] A clinical response of more than 1 year was also observed in a patient with *PTEN*-mutated HS treated with sirolimus.[525] Immune checkpoint inhibition with pembrolizumab and nivolumab has also been used in cases with PD-L1 expression with variable success.[526-528] Other agents that have been used in the therapy of HS include imatinib,[529] sorafenib, and bevacizumab.[522]

Differential Diagnosis

The differential diagnosis of HS is broad and requires careful assessment of morphology and immunohistochemical markers to establish histiocytic lineage and exclude other non-hematologic and hematologic tumors. Nonhematopoietic malignancies such as carcinoma and melanoma can be excluded by expression of cytokeratins or melanocytic markers. Anaplastic large cell lymphoma expresses CD30, and an expanded panel of B-cell and T-cell markers can be useful in the exclusion of B-cell and T-cell lymphoma.

Extramedullary presentations of acute myeloid leukemia may be indistinguishable from HS on morphologic and immunophenotypic grounds; therefore, correlation with the clinical presentation, including bone marrow and peripheral blood findings, may be necessary, as well as with relevant molecular investigations.

Langerhans Cell Sarcoma

Definition

LCS is a rare malignant histiocytic/dendritic neoplasm that is characterized by malignant histologic features and immunophenotypic evidence of Langerhans cell differentiation. It has an aggressive clinical behavior and shows a poor prognosis, with a median overall survival of 19 months.[530]

Synonyms and Related Terms

Langerhans cell sarcoma (ICC); Langerhans cell sarcoma (WHO 5th ed.); Langerhans cell sarcoma (WHO Revised 4th ed.); Primary/secondary malignant histiocytosis, Langerhans cell subtype (Revised Classification of the Histiocyte Society, 2016).

Epidemiology

The overall incidence of the disease in the United States has been reported as 0.2 per 10,000,000 with a median age at diagnosis of 62 (range, 19–90) years.[530] Secondary cases have been described, usually after or concurrent with a diagnosis of lymphoid malignancy, including FL,[477,483,531] chronic lymphocytic leukemia,[478,532] hairy cell leukemia,[533] marginal zone lymphoma,[534] and T-lymphoblastic leukemia.[411] LCS has also been reported in the setting of chronic myeloid leukemia on imatinib, although the LCS did not have the

BCR::*ABL1* fusion.[535] Rare cases have been reported after a diagnosis of LCH.[536] Notably, some cases were classified as LCS in the literature with CD1a expression alone, thus the possibility of indeterminate dendritic cell lineage is not excluded in these lesions.

Clinical Features

The most commonly affected sites are the connective tissue, bone marrow, lymph nodes, skin, liver, and spleen.[530,537] The disease can be localized and involve a single site or be widely disseminated.

Morphology

LCS is characterized by cytologic features of malignancy including nuclear pleomorphism and anaplasia, and a high mitotic rate with atypical mitoses.[2] The nuclear features may resemble cases of LCH with nuclear grooves, convoluted nuclei, and eosinophilic cytoplasm (**Fig. 52-25A**). Occasional eosinophils may be present, but accompanying inflammatory cells are usually few. Mitotic activity is usually conspicuous and the proliferation index in the atypical cells is moderate to high.

Immunophenotype

The atypical cells must show evidence of a Langerhans cell phenotype and demonstrate some expression of S100, CD1a, and langerin (CD207); however, this is often variable and the percentage of CD1a/langerin (CD207) positive cells needed to diagnose LCS is not well-defined (**Fig. 52-25B**). In some cases, these markers may only be present in a minor subset of the tumor cells. Expression can also differ between biopsies from the same patient and loss of some of the diagnostic markers can occur during the course of the

disease.[411] LCS also variably expresses CD68, CD4, and lysozyme, and is negative for follicular dendritic cell markers CD21 and CD23.[538] Very rarely, expression of CD3,[539,540] CD30, and CD56,[541] as well as other T-cell markers,[540] has been reported. BCL6 expression has been reported in some secondary cases.[531]

Genetics and Molecular Findings

A recent molecular study of 10 cases of LCS (including three with a history of lymphoma) has shown frequent and apparently mutually exclusive mutations in *CDKN2A* (50%) and *TP53* (40%). Alterations in the MAPK pathway were also frequent, occurring in 90% of cases, and included mutations in *KRAS, BRAF* p.V600E, *MAP2K1,* and *PTPN11*. *PTEN* alterations were also identified in three MAPK pathway-mutated cases.[494] Case reports have also described *TP53* mutation co-occurring with both *PTPN11* and *NRAS* mutations, and with a *KRAS* mutation in primary LCS,[540,542] one of these also had a homozygous loss of *CDKN2A*.[540]

Other studies have confirmed MAPK pathway mutations in secondary LCS. A *BRAF* p.V600E[532] mutation has been described in LCS after CLL/SLL and a *KRAS* mutation has been reported in LCS after FL.[483] In both of these cases, the MAPK pathway activating mutation was only identified in the LCS component.[483,532] In a rare case of clonally related LCS that preceded the lymphoid malignancy (CLL/SLL),[543] both LCS and CLL/SLL components shared alterations in *MAP2K1, NRAS,* and *CDKN2A*.

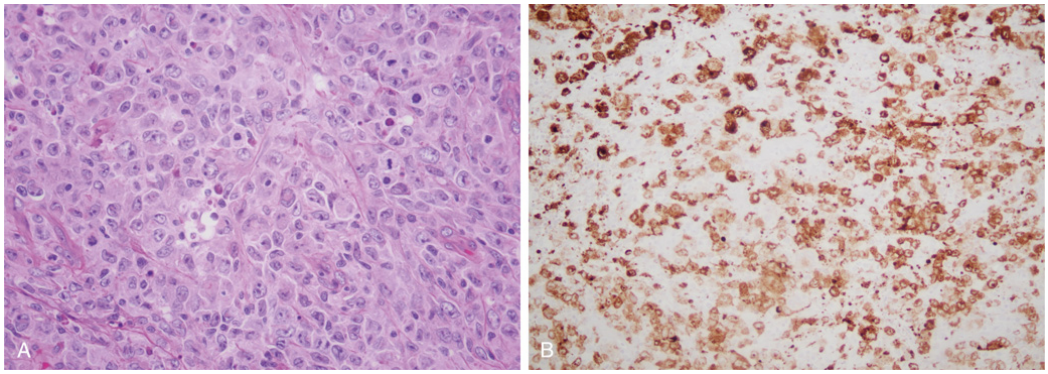

FIGURE 52-25 Langerhans cell sarcoma.A, The neoplastic cells have nuclear grooves, convoluted nuclei, and eosinophilic cytoplasm with atypical cytologic features and conspicuous mitotic activity. **B,** Langerin is expressed.

A common clonal origin has been shown in cases associated with lymphoid malignancy through shared IG or TR gene rearrangements[411,478,533,534] and shared cytogenetic abnormalities,[532,534] including shared *IGH*::*BCL2* rearrangements in cases associated with FL.[483,531] Furthermore, cases associated with low-grade B-cell lymphoma have also been shown to harbor mutations in genes that are typically mutated in B-cell lymphoma, such as *CREBBP, KMT2D,* and *TNFRSF14*.[494] Although comparative NGS studies have not been possible in all cases, at least some of these mutations may be common to both lymphoid and LCS components.[483]

Clinical Course and Prognosis

Treatment strategies are not well established and have included surgical excision of local disease or multimodality therapy, including

radiotherapy and diverse chemotherapy regimens.[537] Recent case reports have shown variable success with novel agents including anti-PD1 therapy in the setting of PD-L1 expression, and BRAF or MEK inhibitors in *BRAF* p.V600E mutated cases.[487,542]

The prognosis is generally poor. A recent analysis has shown a 1-year overall survival rate of 62%, with a median overall survival of 19 months.[530] Previously, overall disease specific survival for all patients was estimated at 28% at 5 years in one study; in the case of single organ involvement (local disease), 5-year disease specific survival was 70%, dropping to 15% for loco-regional disease, and no patient with disseminated disease survived to 5 years.[537]

Differential Diagnosis

The immunophenotype of LCS is similar to that of LCH; however, LCS should show frank pleomorphism and cytologic atypia and an increased mitotic rate, allowing distinction. Expression of langerin aids in the distinction from other subtypes of histiocytic neoplasia.

Interdigitating Dendritic Cell Sarcoma

Definition

IDCS is a neoplasm derived from the interdigitating dendritic cells, the accessory cells found in the T-cell areas of peripheral lymphoid tissue, including the paracortical areas of lymph nodes and periarteriolar sheath of the spleen.[544]

Synonyms and Related Terms

Interdigitating dendritic cell sarcoma (ICC); Interdigitating dendritic cell sarcoma (WHO 5th ed.); Interdigitating dendritic cell sarcoma (WHO Revised 4th ed.); Primary/secondary malignant histiocytosis,

interdigitating dendritic cell subtype (Revised Classification of the Histiocyte Society, 2016).

Epidemiology

IDCS is an extremely rare neoplasm, with 20 cases recorded in a retrospective review of data from the National Cancer Institute's SEER database spanning the period of 2001 to 2008. The mean age at diagnosis was 64 years, and there was a male predominance.[545] Another pooled analysis of 127 published cases showed a median age of 58 years and a slight male predominance.[546]

IDCS is associated with hematologic malignancy in ~12% of cases[546] and has occurred in patients with CLL/SLL,[478,547,548] DLBCL,[549] FL,[476] NK/T cell lymphoma,[550] and B-lymphoblastic lymphoma.[494,551]

Other, non-hematologic malignancies have been reported in ~7% of patients with IDCS and include carcinoma (liver, gastric, breast, bladder, skin), leiomyosarcoma, and oligodendroglioma.[546]

Clinical Features

IDCS most often presents as isolated nodal involvement of cervical or axillary lymph nodes, but may also involve a variety of extranodal sites including the liver, spleen, skin, bone marrow, and gastrointestinal tract.[552] Some patients have systemic symptoms including fever, weight loss, night sweats, and fatigue.[552]

Morphology

The neoplastic cells are large in size with round, grooved, or indented nuclei and prominent nucleoli and abundant cytoplasm (**Fig. 52-26A**). Some cases may have pronounced nuclear pleomorphism with

Reed-Sternberg–like cells; other cases may be composed of spindled cells with a whorled arrangement.[544] The background is rich in inflammatory cells, particularly small T lymphocytes, but neutrophils, macrophages, eosinophils, and plasma cells can be seen. Necrosis, fibrosis, hemorrhage, and hemosiderin deposition have been described in some cases. The mitotic count is variable and is often low (less than 5 per 10 high-power fields), although higher mitotic counts (>20 per 10 high-power fields) are also described.[552]

Immunophenotype

IDCS is positive with S100 (**Fig. 52-26B**) with variable positivity for CD68, CD163, lysozyme, and CD45 reported. Other specific markers for dendritic cells (CD1a, langerin), FDCs (CD23, CD21), B and T cells, melanoma, and carcinoma are generally negative[547,553] (**Fig. 52-26C**).

Genetics and Molecular Findings

The largest series of IDCS to date has found MAPK pathway alterations in 4 out of 7 (57%) of IDCS, including in *MAP2K1, NRAS, KRAS,* and a *CBL*::*USP2* fusion. Two cases also had *TP53* mutations.[494] One case in this series harbored both *NRAS* and *TP53* mutations and occurred after B-ALL, with both components showing shared clonal IG rearrangements. Another case report has also described IDCS associated with B-ALL with a *MAP2K1* mutation detected in the IDCS, but not in the previous B-ALL. Both components in this case showed identical clonal IG rearrangements and had several overlapping mutations by NGS confirming a clonal relationship.[551]

A common clonal origin has also been demonstrated in cases of IDCS associated with CLL/SLL by the presence of identical IG gene rearrangements and shared cytogenetic abnormalities between the two tumors, including trisomy 12 and 17p deletion.[478,547] The *IGH*::*BCL2* rearrangement has been found in both IDCS and an associated FL,[476] and a shared MYC rearrangement has also been shown in a case associated with DLBCL.[549]

The *BRAF* p.V600E mutation has been detected in a couple of cases,[328,554] one of which also showed clonal IG rearrangements without a known history of B-cell lymphoma. The *IGH*::*BCL2* rearrangement has also been detected in a case without a known history of associated lymphoma.[555]

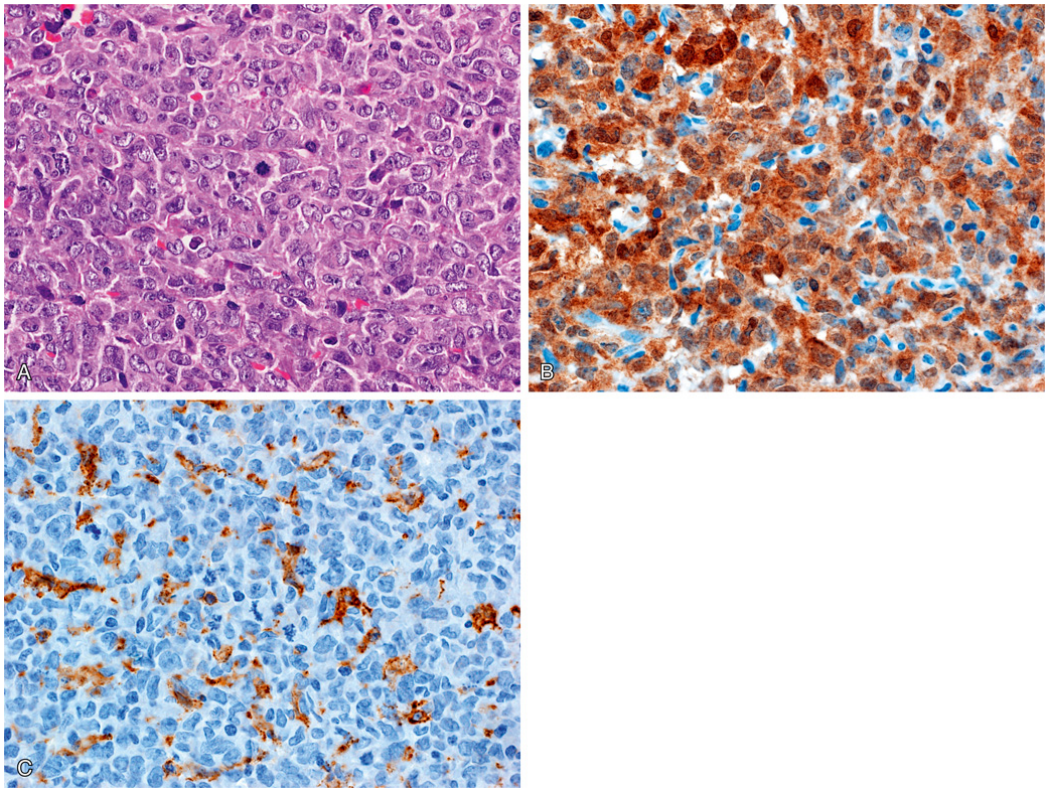

FIGURE 52-26 Interdigitating dendritic cell sarcoma.A, The atypical cells are large with round or indented nuclei, prominent nucleoli, and abundant cytoplasm. Mitotic activity is evident. The cells express S100 **(B)** and are negative for CD163 **(C)**.

Clinical Course and Prognosis

Surgery has been the mainstay of treatment, with some patients receiving radiotherapy or systemic chemotherapy. Recurrence, both local and metastatic, occur in 50%.[546]

Cases are limited, but data suggests the overall prognosis is poor, particularly with disseminated disease. In one analysis, the median overall survival and progression-free survival of IDCS were 12 and 6

months with a disease-specific mortality rate of 36.4%. Mortality rates at 1 year were 21.1% for localized disease and 78.9% for disseminated disease.[546]

Differential Diagnosis

There is considerable overlap with spindle cell melanoma, with one study showing nearly equivalent IHC staining patterns and profiles in the tumors, leading to the question of whether these represent similar or identical processes.[556] Melanoma markers such as MelanA and HMB45 should be negative in IDCS, but a couple of studies have reported SOX10 expression in both diagnoses.[556,557] As distinction between these two entities may not be possible on immunophenotypic grounds, a recent study has noted that analysis of mutation signature by NGS to assess for a UV mutational signature may be helpful in difficult cases.[494]

FDCS may have overlapping morphologic features; however, IDCS is negative for follicular dendritic cell markers such as CD21, CD23, and CD35.[558]

Follicular Dendritic Cell Sarcoma and Epstein-Barr Virus–Positive Inflammatory Follicular Dendritic Cell/Fibroblastic Reticular Cell Tumor

Definition

Follicular dendritic cell sarcoma (FDCS) is a rare, malignant neoplasm of mesenchymal origin that shares histologic and immunohistochemical features, and a similar transcriptional profile, with FDCs.[237,559] This tumor, which may occur in nodal or extranodal sites, is considered to be a low-to-intermediate-grade

sarcoma, although a significant number of cases may show locally aggressive or metastatic behavior.[560]

The related EBV-positive inflammatory follicular dendritic cell/fibroblastic reticular cell tumor (IFDCT) until recently was considered an EBV-associated variant of FDCS but is now considered a distinct clinicopathologic entity in the most current classifications schemes.[240,241,561] IFDCT is discussed together with typical FDCS.

Synonyms and Related Terms

Follicular dendritic cell sarcoma (ICC); Follicular dendritic cell sarcoma (WHO 5th ed.); Follicular dendritic cell sarcoma (WHO Revised 4th ed.).

Epstein-Barr virus-positive inflammatory follicular dendritic cell/fibroblastic reticular cell tumor (ICC); Epstein-Barr virus-positive inflammatory follicular dendritic cell sarcoma (WHO 5th ed.); Inflammatory pseudotumour-like follicular/fibroblastic dendritic cell sarcoma (WHO Revised 4th ed.).

Background

FDCS was first described by Monda et al. in 1986 in their seminal publication of four cases that presented with painless cervical lymphadenopathy.[562] The authors noted the morphologic, ultrastructural, and immunohistochemical similarities to normal lymph node “dendritic reticulum cells,” which are today referred to as FDCs. FDCs are mesenchymal-derived antigen-presenting cells that play a critical role in the immune response and reside in the B-cell germinal center. (For comprehensive reviews of FDCs and their relationship to FDCS, the reader is referred to two recent reviews.[238,239]) Subsequently, in 1996, the same group reviewed the

existing literature and reported an extended series of cases that they designated at that time as *Follicular Dendritic Cell Tumors*, and found that extranodal presentations accounted for 37% of cases.[563] The most recently updated information, published in 2021, reported that 79.4% (of 809 cases) were extranodal,[239] although this percentage may be high because of publication bias for unusual locations where this diagnosis is not expected. Nonetheless, it appears that extranodal locations account for the majority of cases.

IFDCT was first reported as a clinicopathologic variant of FDCS in 2001, characterized by frequent involvement of spleen and liver, a female predominance, an intense inflammatory infiltrate, and the presence of EBV in the tumor cells.[564] IFDCT was recognized as a distinct entity in 2016 in the WHO revised 4th edition.[561]

Epidemiology

FDCS occurs primarily in adults with a median age of 49 years,[552] but has been reported in children as young as 6 years of age.[565] There is no gender bias associated with the typical form of FDCS; however, there is a strong female prevalence in patients with IFDCT.[564] Although FDCS only accounts for 0.4% of all soft-tissue sarcomas,[566] it has been reported from nearly every geographic region in the world. Though the typical form has not been associated with known cancer viruses, IFDCT is characterized and defined by its association with EBV infection.[564]

Clinical Features

The clinical presentation of typical FDCS varies depending on the site of involvement, which can be both nodal or extranodal, as noted earlier.[239] The most common sites of lymph node disease are

cervical, axillary, mediastinal, and abdominal. Patients with localized cervical or axillary lymphadenopathy commonly present with a slow growing, painless swelling of the affected region and are usually diagnosed early. Patients with mediastinal tumors may present with cough or difficulty swallowing, while patients with abdominal lymph node disease tend to present with vague abdominal pain and develop sizable tumor masses before a diagnosis is established. Patients with extranodal disease are more likely to present with generalized systemic symptoms including weight loss, lethargy, night sweats, and fever, particularly those with IFDCT affecting liver or spleen.[552,567]

A subset (5%–10%) of typical FDCS has been associated with the hyaline vascular variant of Castleman disease.[568-572] These cases suggest a common link between the follicular dendritic cell component of Castleman disease and the tumor cells of FDCS, which is also supported by their shared transcriptional profile.[559] In addition, some cases with spatially coexisting diseases show clear transitions between the Castleman disease component and the FDCS component, often containing atypical dendritic cells that merge into regions of FDCS. Further evidence of a link between the two diseases is a recently reported case of FDCS with a *PDGFRB* p.N666S mutation,[494] a variant that has been reported in 10% to 20% of Castleman disease cases.[573]

Rare cases of FDCS have also been associated with paraneoplastic pemphigus and less commonly with myasthenia gravis.[574-580] FDCS should be seriously considered in patients presenting with pemphigus and a mass lesion.

In addition to the strong female gender bias and EBV involvement, IFDCT exclusively affects extranodal sites. Although the liver and

spleen were the first sites of involvement to be recognized,[564] other visceral sites of involvement include bowel, bladder, and tonsils.[581-585] Despite its visceral location and frequent multiorgan involvement, IFDCT is generally indolent and has a low rate of recurrence after treatment, unlike typical FDCS.[567] These clinicopathologic differences have justified its classification as a distinctive clinicopathologic entity despite the apparent common cellular origin.

Morphology

FDCS grows as a solid, well-circumscribed mass and can reach a very large size, up to 20 cm or more, particularly in tumors that occur in the retroperitoneum or mediastinum. The tumors are generally described as firm, but the larger tumors may have areas of hemorrhage and necrosis.

Histologically, FDCS tumors are comprised of spindled-to-ovoid-shaped tumor cells that can show a variety of architectural growth patterns. Tumors may grow diffusely with little pattern, or more typically they may have a fascicular, storiform, or whirling growth pattern, the latter often described as resembling the growth pattern of meningioma (**Fig. 52-27A–B**).[562,586]

Cytologically, the tumor cells have eosinophilic cytoplasm with indistinct borders, and nuclei with finely dispersed chromatin containing small but distinct nucleoli (**Fig. 52-27C**). Although the tumor cells generally show little atypia and few mitoses, some tumors will display nuclear atypia and a higher number of mitoses. Binucleate and occasionally multinucleate cells may be present (**Fig. 52-27D**). These are reminiscent of the binucleated FDCs that are

frequently seen in reactive germinal centers, and, when present, can be helpful in recognizing FDCS. Nearly all cases of typical FDCS will have a background of small lymphoid cells that are interspersed among the tumor cells. Cases that have large numbers of lymphocytes, particularly those that may present in the mediastinum, have been mistaken for thymomas.[586]

As its name suggests, IFDCT is notable for the very intense inflammatory cell infiltrate that, in addition to lymphocytes, may contain neutrophils and plasma cells (**Fig. 52-28A**). EBV is invariably present in the neoplastic tumor cells and is a requisite for this diagnosis (**Fig. 52-28B**). The inflammatory infiltrate may be so dense as to obscure the neoplastic spindle cell population and make its recognition difficult if this entity is not considered in the differential diagnosis, and result in its confusion with other types of inflammatory pseudotumors, or metastatic/ectopic thymoma. Once IFDCT enters into the differential diagnosis, it can be confirmed by IHC for FDC markers and detection of EBV.

Photomicrograph [A] courtesy of Dr. Annapurna Saksena.

Immunophenotype

The immunophenotype of FDCS is similar to that of normal FDCs.[333,504] The most useful and widely available markers in the clinical laboratory are CD21, CD23, and CD35, and a diagnosis of FDCS requires at least one of these markers to be positive (**Fig. 52-29A–B**). The majority of cases are also positive for CXCL13 (**Fig. 52-29C**),[333,587] clusterin,[588,589] and podoplanin.[590] More recently, two new markers, FDC-secreted protein (FDCSP) and serglycin (SRGN), were identified by whole transcriptome sequencing and found to be highly specific and sensitive for FDCS by IHC.[591] CD45 and the common lineage-specific B-cell and T-cell markers are negative.[504] Markers that are common in histiocytic tumors such as CD1a, lysozyme, langerin, and CD163 are usually negative, although CD68 may be positive in some cases.[504] The immunophenotype of IFDCT is identical to that of typical FDC except for the presence of EBV-related markers such as LMP1 or EBV-encoded RNA, which are unique to IFDCT.

Genetics and Molecular Findings

There is limited information regarding the molecular pathogenesis of FDCS and virtually none regarding IFDCT. As expected in a tumor derived from a mesenchymal nonhematopoietic precursor cell, these tumors do not usually have immunoglobulin or T-cell receptor gene rearrangements, although there are occasional reports to the contrary.[519,592] Early studies using EBV terminal repeat analysis of IFDCT provided the first formal proof that these lesions were a clonal tumor[593] and subsequent cytogenetic studies in typical FDCS confirmed its clonal nature.[594-597] These later studies revealed

complex alterations, some suggesting involvement of tumor suppressor gene loci; however, no recurrent cytogenetic abnormalities have been reported.

Molecular genetic studies are few in FDCS, but several themes appear to be emerging. Unlike most of the histiocytic tumors, mutations in the MAPK pathway are not common. Although an initial early study reported *BRAF* p.V600E mutations in 5 out of 27 (28.5%) cases using droplet digital PCR technology,[511] subsequent studies using NGS technology have not confirmed this finding. Rather, these later NGS studies report frequent alterations within the NF-κB pathway, including *NFKB1A, BIRC3, TRAF3, SOCS3, CYLD,* and *TNFAIP3*[494,598,599]; alterations in MAPK pathway genes, including *BRAF* p.V600E, were not detected. Copy number losses at tumor suppressor gene loci *(CDKN2A, RB1, CYLD, BIRC3)* have been recurrently reported in several of the referenced NGS studies, and by MIP array technology in additional cases.[600] Amplification of *CCND2* was reported in four patients from one study,[601] and focal copy gains in *CD274* (PD-L1) and *PDCD1LG* (PD-L2) were detected in three patients from a second study.[598] Intriguingly, a single case with a *PDGFRB* p.N666S variant was reported in the study of Massoth et al.[494] As previously mentioned, this variant has been reported in the hyaline vascular variant of Castleman disease, supporting the hypothesis that some cases of FDCS develop from the FDC component of Castleman disease.[573] No recurrent fusions have been identified, although several rare novel fusions of unknown significance have been reported, including *TYK2*::*ATPAF2*, *MAP3K1*::*GCOM1*, and *NTRK1*::*PDIA3*.[494]

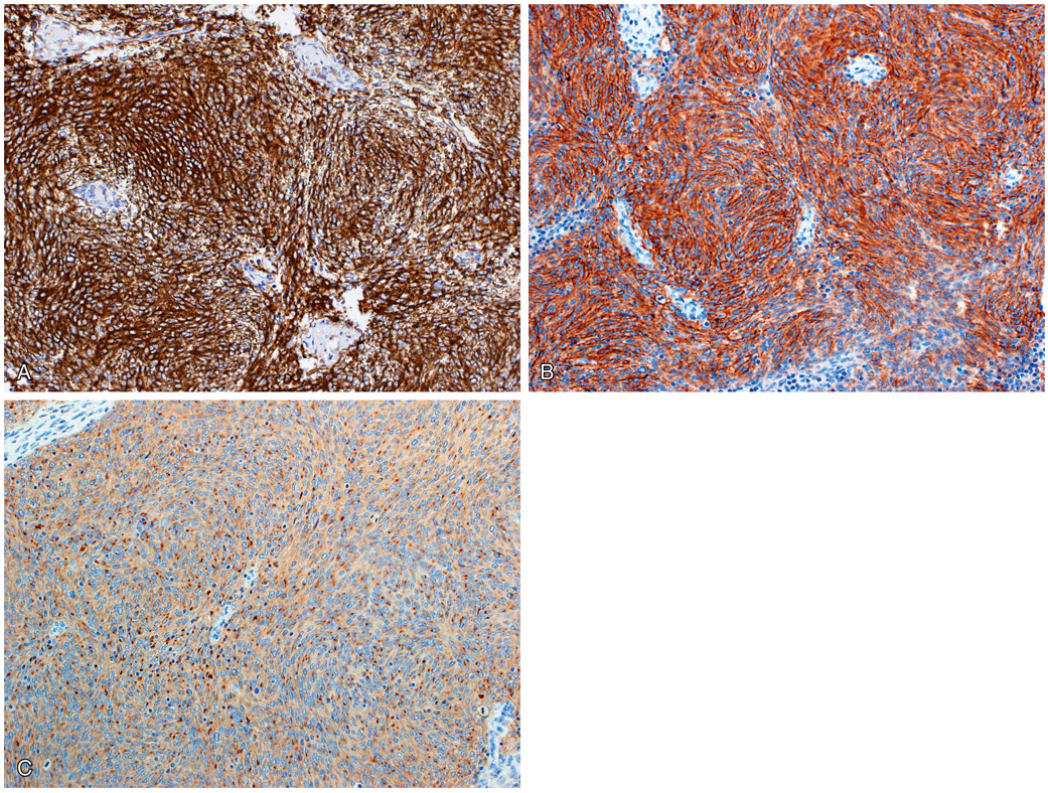

FIGURE 52-29 Follicular dendritic cell sarcoma (FDCS) immunophenotype in a typical FDCS with spindle cell morphology showing strong expression of CD21 **(A)**, CD23 **(B),** and CXCL13 **(C)**.

The molecular profile of IFDCT is unknown. Bruehl et al. subjected two IFDCT cases to large-panel NGS sequencing and did not find pathogenic variants, including fusions.[602] This is consistent with our own experience as well (unpublished data). However, it should be noted that the inability to detect mutations may be because of the small number of tumor cells present, which may be beyond the resolving power of the NGS assays.

Clinical Course and Prognosis

Typical FDCS is generally considered a low-to-intermediate-grade tumor with unpredictable behavior.[240,241] They have a propensity for local recurrence if not excised completely, and a subset may metastasize.[560] Small lesions can be surgically removed, and the risk of recurrence is low. Lesions greater than 5 cm have a higher rate of recurrence and distant metastases.[560,603] There is no universally accepted staging system that predicts the behavior of these tumors; however, using retrospective data, Li et al. developed a risk assessment model for extranodal FDCS based on mitotic rate, tumor size, and histologic grade.[603] Lesions were defined as low, intermediate, and high risk and were associated with recurrence rates of 16%, 46%, and 73% and mortality rates of 0%, 4%, and 45%, respectively. This system has yet to be tested in a prospective trial but is a notable attempt to develop a histology-based system for predicting the biological behavior of these tumors.

There is no single treatment recommended for typical FDCS and the therapeutic approach is generally tailored to the presentation of the disease. As previously mentioned, localized tumors are surgically removed and may be accompanied by adjuvant chemotherapy or radiation therapy, while disseminated disease is generally treated with a combination of surgery, systemic chemotherapy, or radiation.[604,605] Newer biological therapies have been successful in rare cases but are anecdotal.[606,607] Interestingly, despite the visceral presentations of IFDCT, these cases tend to behave indolently, and therefore conservative approaches may be appropriate.[567]

Differential Diagnosis

The differential diagnosis of FDCS varies by location. Cases that are limited to lymph nodes have a narrower differential diagnosis and would include mainly primary tumors of lymph nodes such as IDCS and the very rare fibroblastic reticular cell sarcoma.[562,586] Once FDCS is considered, the characteristic FDC immunophenotypic profile is highly specific.

In extranodal sites, the differential diagnosis is broader, and, depending on the specific location, might include gastrointestinal stromal tumor, metastatic thymoma, ectopic/metastatic meningioma, spindle cell carcinoma, or other soft tissue sarcomas.[565,601]

IFDCT (as well as typical FDCS with large numbers of inflammatory cells) can be further confused with other tumors and conditions that have high percentages of inflammatory cells. These include ALK-positive histiocytosis, inflammatory myofibroblastic pseudotumor, and lymphocyte-rich metastatic thymomas.[585] A high degree of suspicion and the presence of FDC markers CD21, CD23, or CD35 are key to distinguishing FDCS from other tumors, and the associated presence of EBV will further distinguish IFDCT.

Acknowledgment

The authors and editors dedicate this chapter to the memory of Ronald Jaffe, who wrote the Langerhans histiocytosis chapters in the two previous editions of this book.

Pearls and Pitfalls

Hemophagocytic Syndromes

- The clinical syndromes and morphology of primary and secondary hemophagocytic lymphohistiocytosis (HLH) are similar.
- A careful genetic history, testing for perforin expression and natural killer (NK)-cell number and function, and molecular analysis may be necessary to distinguish them.
- The presence of hemophagocytosis has limited diagnostic sensitivity and specificity, because it may not be always present and it can be observed in patients without HLH.
- The diagnosis of HLH is a complex process that must be carried out rapidly, given the lethality of the disease, excluding mimicking conditions whose pathogenesis differs from that of authentic HLH, thus requiring appropriate therapies.

Storage Disorders

- The diagnosis of Gaucher disease is established by identifying histiocytes with increased iron uptake and cytoplasmic wrinkled-paper appearance (Gaucher cells) in the bone marrow or any other tissue, in association with decreased activity of β-glucocerebrosidase in leukocytes.
- Histiocytes that mimic Gaucher cells can accumulate in the bone marrow of patients with disorders associated with high cell turnover, such as chronic myelogenous leukemia.
- The presence of splenomegaly and bone marrow infiltration by Niemann-Pick cells, as well as sea-blue histiocytes in

association with decreased sphingomyelinase activity in leukocytes, confirms a diagnosis of Niemann-Pick disease.

- In Tangier disease, young individuals typically present with enlarged yellow-orange tonsils, and the identification of lipid-laden macrophages accumulated provides a clue for the diagnosis, but is not pathognomonic.

Histiocytic and Dendritic Cell Neoplasia

- The diagnosis of histiocytic and dendritic cell neoplasia can be challenging and requires the correlation of the clinical features, appearances on imaging studies, and histopathologic findings.
- Immunohistochemistry is an essential adjunct in the diagnosis of both histiocytic neoplasia and dendritic cell tumors, and plays a key role in distinguishing between the various subtypes of these tumors and excluding potential mimics.
- Molecular evaluation by next-generation sequencing studies and fusion testing allows the detection of activating alterations in MAPK, PI3K/AKT, and NF-κB pathway genes that not only aids in diagnosis but also identifies potential targets for systemic therapy.

Ataxia-Telangiectasia

Primary immunodeficiencies (PIDs) are inborn errors of immunity and comprise 485 different genetic disorders at the time of the most recent interim update by the International Union of Immunological Societies (IUIS) Expert Committee.[1,2] PIDs often predispose to infection and tend to present early in life, with high morbidity and

mortality if left untreated; in fact, they are often diagnosed because of severe, persistent, or recurrent infections during infancy that don't respond to therapy. However, it has become apparent that PIDs not only confer risk for developing infections, but increasingly they are associated with immune dysregulation, autoimmunity, autoinflammation, allergy, and susceptibility for developing malignancies, in particular lymphomas.[3] PIDs are monogenic, caused by a defect in a single gene, not necessarily with complete clinical penetrance, and in the majority of cases tend to cause loss of function (LOF) irrespective of autosomal dominant (AD), autosomal recessive (AR), or X-linked recessive (XR) inheritance. In recent years, gain-of-function mutations have also been described, predominantly in the AD group.[4] However, all mutations are *not* created equal; furthermore, great variability in clinical phenotype (i.e., age at onset, severity, and clinical presentation) can be observed even within the same family because of additional factors that come into play besides the specific characteristic of the causal mutation(s) involved, such as gene dosage; differential allelic expression; copy number variations and other modulatory influences; gene modifier (epigenetic changes); and age, sex, and environmental factors.[1] The importance of the family history in the diagnosis of a possible PID cannot be overstated; however, a negative family history does not exclude PID, particularly for patients with XR disorders, who frequently harbor "new" mutations and do not have affected male relatives.

In the last 15 years, the number of PIDs has increased almost exponentially, largely because of the introduction in 2008 of next-generation sequencing (NGS), expanding the traditional approaches

in classical genetics that used cytogenetic tools such as linkage analysis, positional cloning, and candidate gene approach with Sanger sequencing as the gold standard.[5-7] These new technologies, in particular whole-exome sequencing (WES), which detects mutations in protein-coding and RNA-coding genes, and whole-genome sequencing (WGS), which also analyzes intronic sequences, have also brought new challenges with the detection of many mutations in normal individuals, rendering it even more imperative to validate candidate genes with functional studies and in vivo models. In addition to the more traditional approach using transfection experiments with knockdown of candidate genes in primary cells and cell lines, new approaches using induced pluripotent stem (iPS) cells and gene editing with CRISPR/Cas9 have provided additional and more sophisticated tools to understand the role of candidate genes in the appropriate cellular context and to assess its relevance to the phenotype under study.[6]

As pathologists, it is important to be aware of these disorders and their pathologic features because an accurate and early diagnosis may not only save the life of the patient but that of his or her family members. Complete blood count (CBC) with differential, lymphocyte subset analysis, and quantitation of serum immunoglobulins (Ig) are a good jumping-off point in the diagnostic workup, but often the nature and location of a patient's infections tells a lot about the type of underlying immunodeficiency. This is illustrated well by the susceptibility of patients with phagocyte dysfunction like chronic granulomatous disease to staphylococcal infections, as they have an impaired ability to generate reactive oxygen species because of defects in the NADPH oxidase complex,[8] or *Neisseria meningitidis*

meningitis revealing complement deficiency.[9] Humoral immunodeficiency often results in sinopulmonary infections with encapsulated bacteria or chronic diarrhea and is sometimes uncovered in infants after age 4 to 9 months, after maternal alloimmunity wanes. The T-cell arm of the immune system is not only important for controlling viral and fungal disease but also in helping B cells to be able to produce antibodies, so humoral immunodeficiency accompanies cellular immunodeficiency in diseases like severe combined immunodeficiency (SCID).

It may very well be the pathologist, aware of the systemic nature of these disorders, who puts everything together, recognizing other associated but sometimes overlooked clinical features suggesting a PID, like failure to thrive or rash in an infant. Besides the frequent involvement of not only immune organs (thymus, lymph nodes, bone marrow, and spleen), PIDs also have wide-ranging effects on target organs such as the lungs, gastrointestinal tract, skin, and central nervous system (CNS), either caused by infections (bacterial, fungal, viral, and parasitic), autoimmunity, allergic and inflammatory processes (e.g., vasculitis), or neoplasia. In some of these disorders, there are morphologic and phenotypic features we observe that are either unique or intrinsically related to the underlying genetic defect and lead us to a diagnosis; in other instances, the pathologic changes may be non-specific, but they can help by ruling out some of the other diagnostic possibilities. Lastly, understanding PIDs and their pathophysiology is important because it gives us clues about the functional aspects of the immune system, both innate and adaptive, and their intricate interrelationship, which will ultimately lead to the design and implementation of a more targeted therapeutic approach.

Classification

The classification of molecularly defined PIDs is formally updated every 2 years by the IUIS Expert Committee for Primary Immunodeficiency and provides a clinical and immunologic synopsis, genetic defect when known, and mode of inheritance in table format. In 2021 an interim report was issued and, just days after the 2019 update was published in early 2020, it had already become out of date, with 26 additional novel inborn errors of immunity.[1] The 2022 update added 29 novel gene defects, bringing the total number of inborn errors of immunity to 485—up from 191 in the 2011 biennial update.[2] Depending on the genetic defect, when known, or predominant symptom, it is divided into broad categories as follows: (1) immunodeficiencies affecting cellular and humoral immunity; (2) combined immunodeficiencies with associated or syndromic features; (3) predominantly antibody deficiencies; (4) diseases of immune dysregulation; (5) congenital defects of phagocyte number or function; (6) defects in intrinsic and innate immunity; (7) autoinflammatory disorders; (8) complement deficiencies; (9) bone marrow failure; and (10) phenocopies of inborn errors of immunity. Depending on the prevalent defect and symptoms, some of the inherited disorders are listed under multiple headings. The *phenocopies* category refers to patients (syndromes) presenting with characteristics that are similar to inherited PID but are not caused by a germline mutation, but rather arise from acquired mechanisms such as somatic mutations (see the discussion on somatic mutations in the section on autoimmune lymphoproliferative syndrome [ALPS] later in the chapter) or autoantibody production against cytokines, or immunologic factors

leading to their depletion with subsequent development of PID-like symptoms. It is beyond the scope of this chapter to discuss the entire field of PIDs; our focus will be on a limited number of PIDs with particular emphasis on pathologic features and association with lymphoproliferation and lymphomas.

Synonyms and Related Terms

Inborn Errors of Immunity.

Epidemiology

The overall prevalence of monogenic PIDs is low; however, they vary greatly depending on ethnicity, consanguinity, and specific disorder. For instance, it ranges from 1in600 for selective IgA antibody deficiency to 1in100,000 for SCID or 1in1,000,000 males for X-linked lymphoproliferative syndrome-1 (XLP1). Interestingly, the introduction of newborn screening for the analysis of T-cell receptor excision circles (TRECs), a measure of thymic output, in 11 screening programs across the United States has provided more accurate data on SCID, with a prevalence of 1in58,000. As of December 2018, newborn screening for SCID has been implemented in all 50 states in the United States.[10]

Severe Combined Immunodeficiency

SCID is an extreme form of T-cell deficiency. Depending on the gene defect, they are associated with the absence or presence of B cells and natural killer (NK) cells, and, in some instances, they are associated with nonimmunologic manifestations such as

radiosensitivity and skeletal or neurologic abnormalities.[1] This is a very heterogeneous group involving several different genes important in T-cell development with deleterious mutations involving VDJ recombination (*RAG1* and *RAG2, DCLRE1C, PRKDC, NHEJ,* and *LIG4*) and with other severe maturation defects (*ADA, AK2,* and *PNP*).[11] In addition, profound genetic T-cell lymphopenias (combined immunodeficiency) may be considered within the spectrum of SCID because of their similar clinical presentation, and include mutations involving cytokine signaling (*IL2RG, IL7R,* and *JAK3*) and T-cell receptor signaling (*CD3D, CD3E,* and *CD3Z*) or motility (failure of thymic egression) *(CORO1A)*. Leaky SCIDs result from hypomorphic mutations in some of these genes (including *RAG1* and *RAG2*), which allow some degree of T-cell development because of residual activity, but retain impaired T-cell–mediated immunity.[12,13] In typical SCID, the diagnosis is based on absence or a very low number of autologous T cells (less than 300/μL) and very low T-cell function (PHA stimulation less than 10%), frequently with T cells of maternal origin present (maternal engraftment); TREC levels are also undetectable or extremely low at birth.[14] Leaky SCID and some of the profound T-cell lymphopenias may have normal or even an increased number of circulating T cells associated with severe immune dysfunction leading to a similar clinical presentation, but often with a delayed onset and unusual symptoms such as autoimmunity, granulomatous inflammation, skin disease, and increased risk for lymphoproliferative malignancies.[15-18]

Infants with SCID, although normal at birth, present early in life with respiratory tract infections (*Pneumocystis jirovecii,* cytomegalovirus [CMV], adenovirus, parainfluenza type 3, and

respiratory syncytial virus) that are often severe, prolonged, and complicated, or persistent bronchiolitis. Other symptoms include diarrhea, failure to thrive, or thrush. On physical examination, no lymph nodes are palpable, and imaging studies reveal lack of a thymic shadow. Adopting TREC analysis (originally used in HIV patients to monitor new T-cell output) for newborn screening was implemented in order to detect these disorders before symptoms develop so patients can rapidly receive appropriate medical treatment, avoid live vaccines and nonirradiated blood products, and ultimately reconstitute their immune system with lifesaving allogeneic hematopoietic stem cell transplantation (HSCT), or gene therapy.[19-20] Untreated SCID is typically fatal before the patient's second birthday.

In general, despite some false positives (deemed acceptable given the severity of the disease being screened for), TREC analysis has been very successful in identifying typical SCID and most of the profound T-cell dysfunctions, but exceptions exist, including delayed-onset SCID, for which the diagnosis may be delayed.[21]

The Thymus in SCID, CID, and Leaky SCID

Histologic and immunophenotypic characterization of the thymus in these severe PIDs gives us clues to understand their pathophysiology. Various histologic patterns (i.e., dysplastic depleted, dysplastic nondepleted, and nondysplastic nondepleted) have been described based on the distribution of thymic epithelial cells (TECs), thymocytes, and their functional subsets including natural T-regulatory cells (nTregs), dendritic cells, and macrophages,

and they correlate with the underlying genetic defect affecting T-cell development (**Fig. 53-1**).[16,22-25]

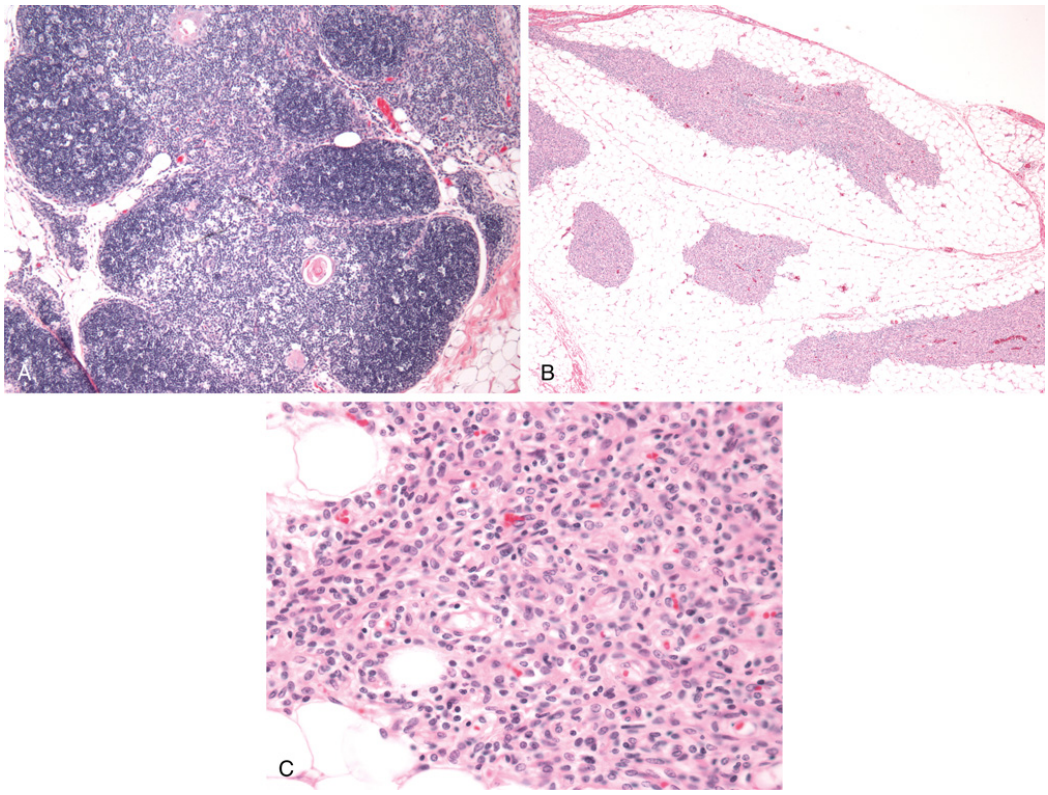

FIGURE 53-1 Example of thymus histology in primary immunodeficiency.A, Normal thymus showing normal lobular architecture with well-defined cortex and medulla with Hassall bodies. **B–C,** Hypomorphic "leaky" SCID with *RAG-1* mutation. Thymus showing fatty tissue infiltration of the lobules, loss of corticomedullary differentiation, and absence of Hassall bodies with a moderate number of thymocytes consistent with a dysplastic depleted thymus caused by a hypomorphic, partially permissive defect.

Omenn Syndrome

One of the exceptions that can be missed by TREC analysis is Omenn syndrome, in which T cells can be present in normal numbers or even increased because of hypomorphic mutations (leaky defect) occurring in a variety of genes involved in VDJ recombination (*RAG1, RAG2, DCLRE1C, LIG4, RMRP,* and *ADA*).[26] They allow some degree of maturation of a very limited number of thymic T cells with a limited repertoire reflected in oligoclonal expansion in the periphery.[27,28] Omenn syndrome was originally described by Gilbert Omenn in 1965 as a syndrome characterized by a profound immunodeficiency with severe erythroderma, lymphadenopathy, and eosinophilia.[29] Omenn syndrome shares a similar clinical presentation with typical SCID (i.e., presents in infancy with pneumonitis, chronic diarrhea, and failure to thrive); however, the presence of adenopathy, hepatosplenomegaly, and generalized erythroderma associated with increased IgE levels and eosinophilia are distinguishing features. In contrast to typical SCID, the persistent presence of inflammation leads to an increased number of circulating T cells with an activated phenotype and inability to proliferate in response to mitogens. Morphologically, lymph nodes show complete effacement of the architecture with a depleted appearance and increased numbers of dendritic cells and eosinophils; they usually lack primary and secondary B follicles. Phenotypically, CD3-positive T cells express CD45RO, CD4, GATA-3, and CD30 with a cytokine profile consistent with a Th2-type response (Figs. **53-2**, **53-3**).[30-32]

One of the protective effects of this type of response against persistent inflammation is the upregulation of nTregs; however, these are severely reduced because of thymic dysplasia with

profound abnormalities of thymic epithelial cell differentiation affecting central tolerance. All these factors contribute to autoimmunity and inflammation in Omenn syndrome.[23,33,34]

Combined Immunodeficiency Generally Less Profound Than SCID

Class-switch recombination (CSR) deficiencies or hyper IgM (HIGM) syndromes are characterized by normal or elevated serum IgM and low or absent serum levels of other Ig classes. In the adaptive immune system, antibody-mediated immune responses are either T-cell independent, in which B cells proliferate upon encountering specific antigens and secrete IgM, or T-cell dependent, and to generate high affinity antibodies, B cells undergo clonal expansion, affinity maturation through somatic hypermutation (SHM), and CSR. These latter events take place within the germinal centers of secondary lymphoid organs upon T-cell–B-cell interaction mediated through CD40-ligand (CD40L) and CD40. Germline mutations can affect CD40/CD40L and CD40-signaling pathways, as well as enzymes involved in double-stranded DNA breaks and repair that occur during CSR.

CD40L Deficiency or Hyper IgM Type 1 Syndrome

CD40L deficiency (XL) or HIGM type 1 defect involves CD40L, which is expressed on activated T cells in a tightly controlled manner, but it is not lethal to T cells.[35,36] Originally thought to be a defect in isotype switching, it is now known to be a defect of T-cell priming, help, and function leading to impaired class switching, best classified as a combined immunodeficiency rather than a

predominantly antibody deficiency.[37] About 200 cases have been described in the literature. It presents with recurrent upper and lower respiratory tract involvement caused by opportunistic infections (*P. jirovecii,* cytomegalovirus, *Cryptococcus, Histoplasma*, and *Candida*), diarrhea when infectious often caused by *Cryptosporidium parvum* (80%), and neutropenia before age 2 years. Subsequent complications involving the biliary tree and liver are often related to persistent *Cryptosporidium* and *Giardia* infections of the biliary system, leading to sclerosing cholangitis, hepatitis, cirrhosis, and increased gastrointestinal malignancies including cholangiocarcinoma. Immunologic features include very low serum levels of IgG and IgA with normal to increased IgM, decreased number of memory B cells, and limited-to-unswitched memory B cells (CD27 positive, IgM positive, IgD positive) in keeping with defects in CSR. Although the number and distribution of T-cell subsets is not affected, CD40L deficiency affects their costimulatory functions for T cells, B cells, and macrophages.[38] Dendritic cell signaling is also affected. Lymph nodes are usually small with IgM/IgD-positive B cells in the far cortex lacking secondary B follicles with minimal-to-absent dendritic meshworks, and well-preserved T-cell areas (**Fig. 53-4**). CD40 deficiency (AR) HIGM type 3 is similar in all respects to HIGM type 1.[37,39]

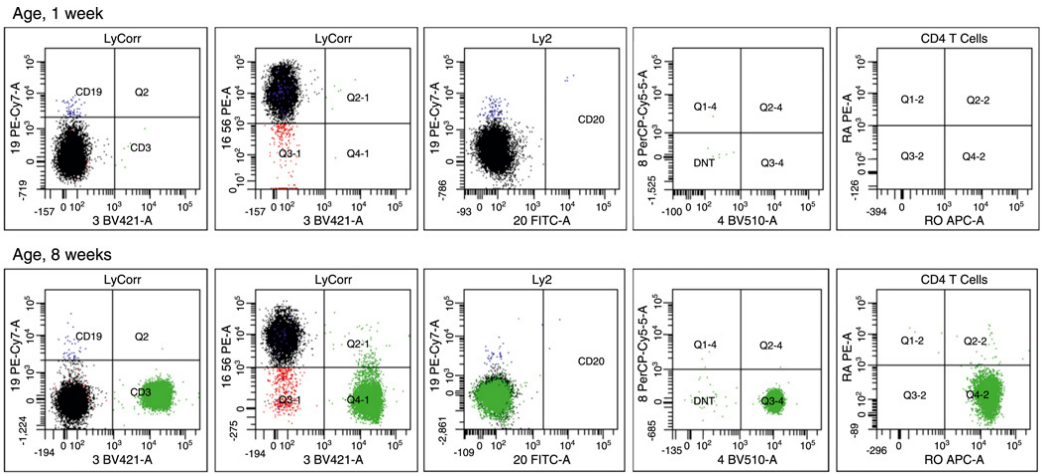

FIGURE 53-2 Omenn syndrome. Flow cytometry: Newborn baby with an abnormal TREC screen and absent T cells *(green)* and B cells *(blue)* and increased NK cells *(black)* developed a progressive rash, eosinophilia, and increased IgE and was ultimately diagnosed with Omenn syndrome with two mutations in *RAG1*. Lymphocyte subset analysis at age 8 weeks revealed engraftment of maternal T cells that were CD4-positive and expressed CD45RO.

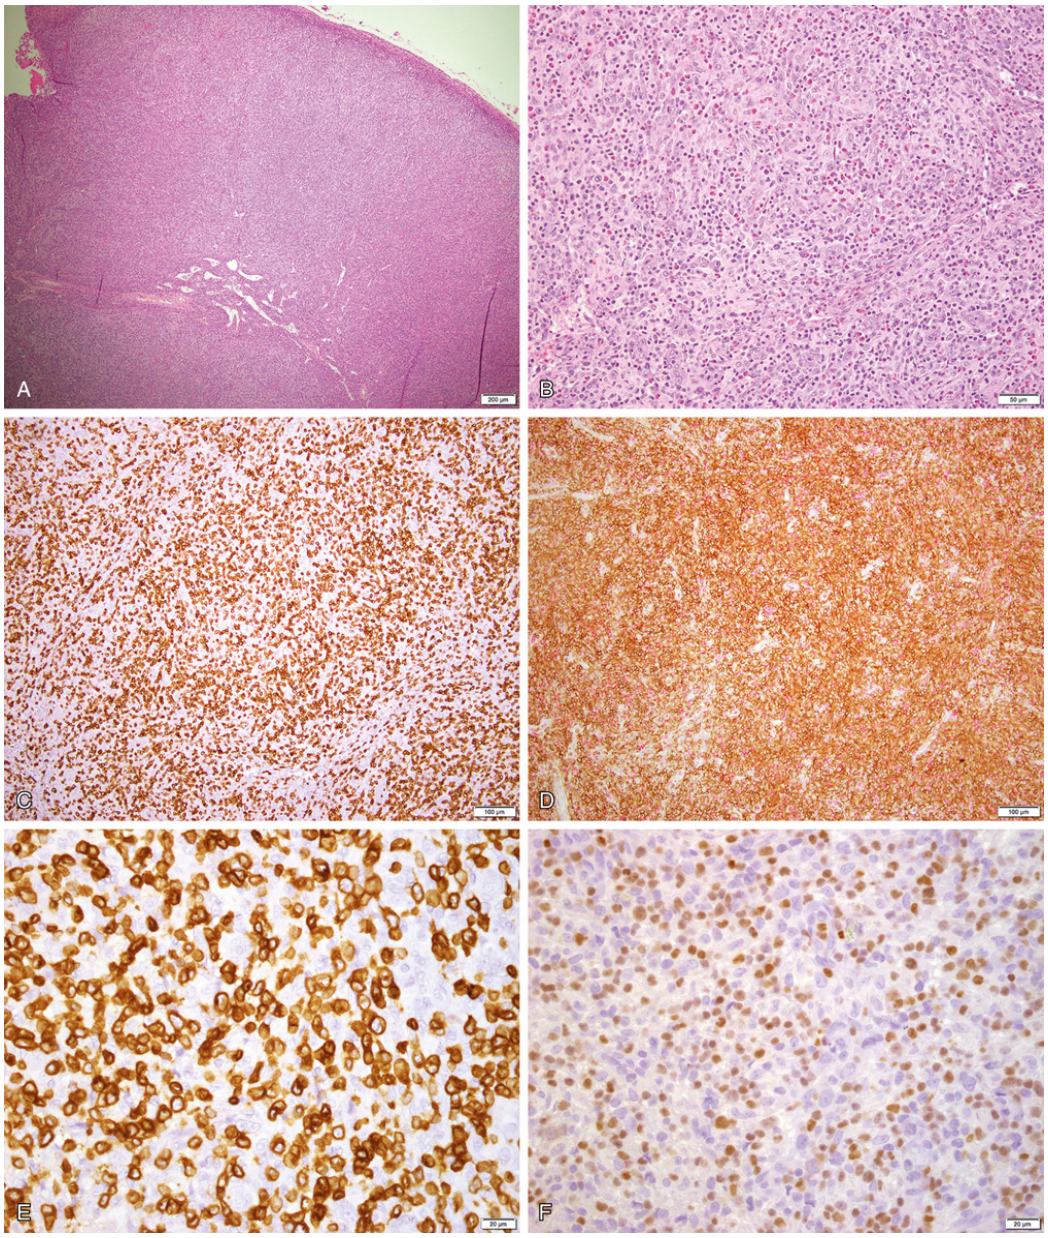

FIGURE 53-3 Lymph node biopsy from a 5-month-old baby boy diagnosed with Omenn syndrome carrying RAG-2 mutations. **A,** Paracortical hyperplasia with lack of B-follicles (hematoxylin and eosin [H&E], ×4). **B,** A polymorphic proliferation composed of small lymphocytes, immunoblast-like cells, and

numerous eosinophils (H&E, ×20). The majority of the lymphoid cells is composed of CD3-positive T cells (**C,** CD3, ×10) with a predominance of CD4 (**D,** double-stain CD4/CD8, ×10). High magnification for CD3 (**E,** ×40) to highlight the cytologic atypia and typically positive for GATA-3 positive cells (**F,** ×40). TCR gamma gene rearrangement is polyclonal/oligoclonal.

AID Deficiency or Hyper IgM Type 2 Syndrome

Patients with activation-induced cytidine deaminase (*AICDA* gene) AID deficiency (AR)/HIGM type 2 syndrome (HIGM2) present with lymphadenopathy, enlarged tonsils, and recurrent bacterial sinopulmonary infections, but no opportunistic infections. Morphologically, the lymph nodes are characterized by florid follicular hyperplasia with large, expanded germinal centers.[40] Similar to the other IGHM, they lack switched memory B cells and show profound defects also in SHM, reflecting the underlying genetic defect involving AID, which participates in both the CSR and SHM processes; however, not all AID mutants are associated with defects in SHM; AID C terminal defect (AD) is an example.[41] These observations have led to a better understanding of the complexity of the CSR mechanism. More recently, AID has been implicated not only in B-cell development through CSR and gene activation through demethylation, but also as a candidate gene in inducing genomic instability in other systems.[42]

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) represents a heterogeneous group of disorders with recurrent bacterial infections of the respiratory tract caused by antibody deficiency with severe reduction in at least two serum Ig isotypes with a normal number of or decreased B cells. The underlying genetic defect is unknown in most cases, and it remains a diagnosis of exclusion. Prevalence ranges from 1in10,000 to 1in50,000 (Europe/North America); males and females are affected equally.[43] Most individuals are diagnosed at between 20 and 40 years of age, making it the most common symptomatic PID in adults. Only 10% to 20% have a positive family history (AD greater than AR); most cases are sporadic. A diagnosis of CVID should not be entertained in very young patients, and it must be differentiated from transient hypogammaglobulinemia of infancy, so by definition the onset of immunodeficiency should be at greater than age 2 years; usually a cutoff of 4 years is used.[43] Underlying genetic defects (3% of cases cumulative) predisposing to CVID include defects in *ICOS* (inducible T-cell costimulator), B-cell receptor complex genes (CD19, CD81, and CD21), and CD20, which are monogenic defects. *TACI* (transmembrane activator, calcium modulator, and cyclophilin ligand interactor), found in 8% to 10%, *BAFFR* (B-cell activating factor-receptor), and *MSH5* (mismatch repair gene) are now considered disease-associated rather than causative, because unaffected heterozygous patients have also been described, and the variants are also detected in normal individuals at a prevalence of 1% or more, and thus considered to represent polymorphisms.

Clinically, the symptoms are very heterogeneous, but two major groups can be broadly recognized based on predominant recurrent

infections of the respiratory tract versus inflammatory complications with a variety of autoimmune disorders (22% to 48%), including cytopenias, granulomatous disease, and increased development of malignancy, mainly lymphomas. Splenomegaly is detected in 30% of patients and it is often associated with cytopenias, but hypersplenism is not considered sufficient to explain it, and other functional defects involving T cells and NK cells have been described.[44] Also, inflammatory bowel disease (IBD)-like symptoms are present in one-third of patients, and the liver is also commonly involved with hepatitis-like symptoms (43%) without evidence of viral infection. From a pathology standpoint, the lungs are the major target organ with acute bacterial infections and possible subsequent development of bronchiectasis and noninfectious immune-mediated changes with a lymphocytic interstitial infiltrate, follicular bronchiolitis, and follicular hyperplasia with often "naked" germinal centers and paucity or absence of plasma cells. In addition, a subset of patients may develop granulomatous lymphocytic interstitial lung disease (GLILD),[45,46] and these noninfectious patterns may coexist (**Fig. 53-5**). In the gastrointestinal tract, a celiac disease-like picture is often present with increased intraepithelial T cells, villous blunting, and, typically, absence of plasma cells. However, these changes do not respond to a gluten-free diet. In addition, prominent lymphoid aggregates consistent with nodular lymphoid hyperplasia are noted. In the liver, a periportal lymphocytic infiltrate of possible autoimmune origin can be seen, and it is often associated with nodular regenerative hyperplasia (NRH).[47-50] The frequency of NRH varies in different studies, ranging from as high as 50% based on the

presence of portal hypertension, a known complication of NRH,[47] to as low as 12% or even 5%.[48,49]

Lymph node biopsies in patients with CVID show different patterns of follicular hyperplasia and a paucity of plasma cells, particularly in the medullary cords. Similar to extranodal sites (i.e., lung and gastrointestinal tract), the germinal centers may be more ill-defined, lack mantles, and show irregular outlines; occasionally, progressive transformation of germinal centers may be observed. The presence of ill-defined follicular structures may have led in the past to overdiagnosis of B-cell lymphomas because of the impression of a distorted architecture. Immunophenotypic studies and clonality studies are helpful in clarifying the diagnosis in such cases,[51-53] because these patients do in fact face an increased risk of B-cell lymphomas, ranging from 8.2% in the United States to less than 3.8% in Europe and the United Kingdom. These lymphomas, which tend to occur in the 4th to 7th decades of life, are mostly non-Hodgkin lymphomas of B-cell type including extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue (MALT) type, and often are not associated with Epstein-Barr virus (EBV).[53,54] Risk of lymphoma seems to be the highest (29%) in patients with late-onset CVID associated with a severe T-cell defect,[55] and about 60% in this setting are EBV-associated. It is noteworthy that this subset of patients more frequently also has splenomegaly, granulomatous disease, and enteropathy, all of which are associated with decreased overall survival.

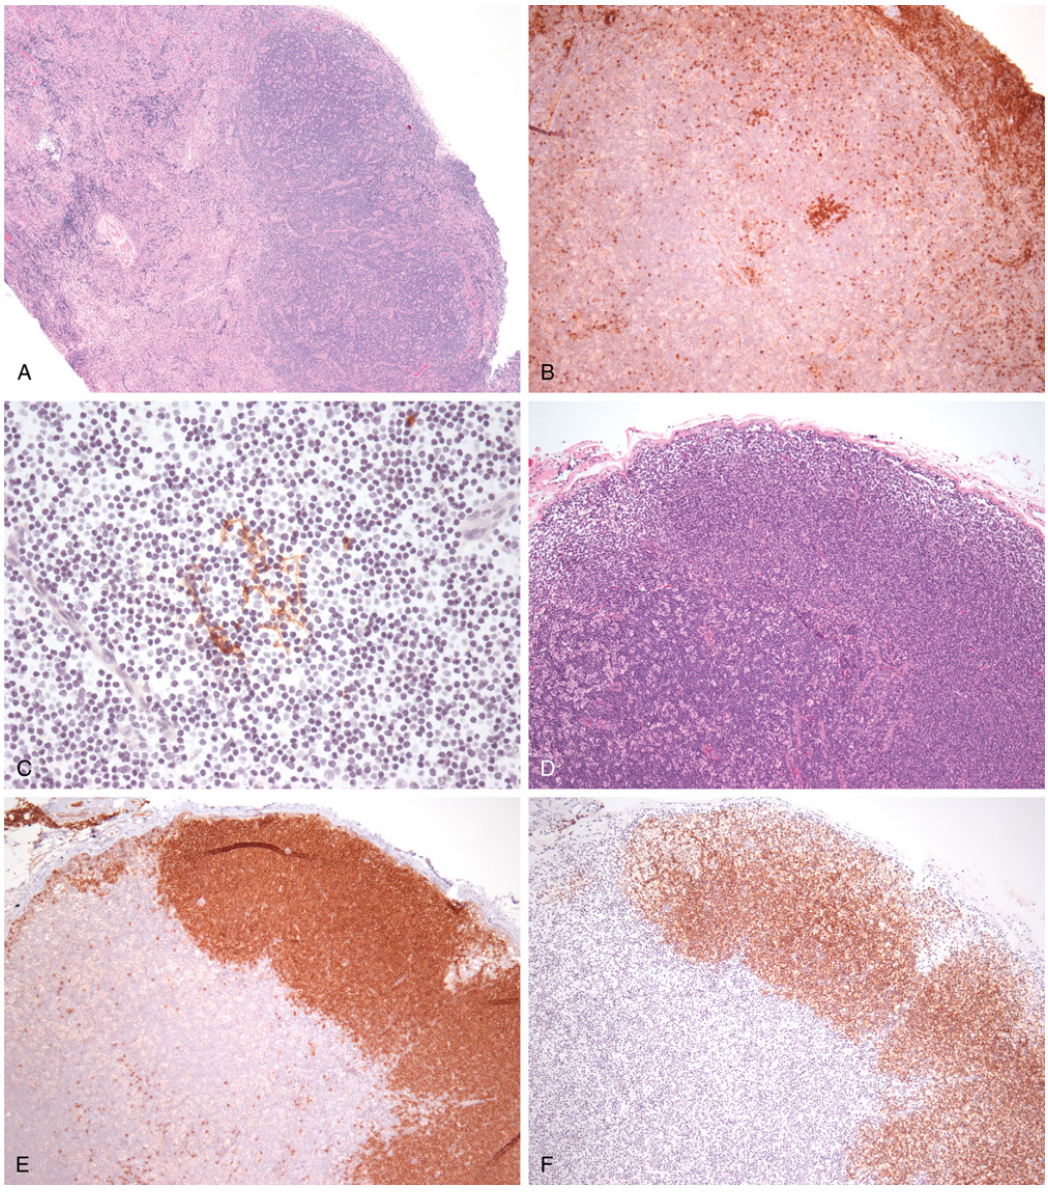

FIGURE 53-4 Two examples of hyper IgM syndrome related to CD40L deficiency.A, Small lymph node with prominent paracortical hyperplasia lacking secondary B follicles in the cortex. Note the fibrosis involving the rest of the node (×4). **B,** Only a few clusters of IgM-positive B cells are noted forming small aggregates with only rudimentary CD21-positive meshworks **(C).**

Hematoxylin and eosin (H&E) uniform cortical areas lacking secondary B follicles adjacent to well-developed T-cell areas **(D)** are shown; the B cells in the cortex are uniformly positive for IGD and IgM, consistent with naïve B cells **(E)**, and they are also positive for CD21 **(F),** but the follicular dendritic meshworks are still rudimentary.

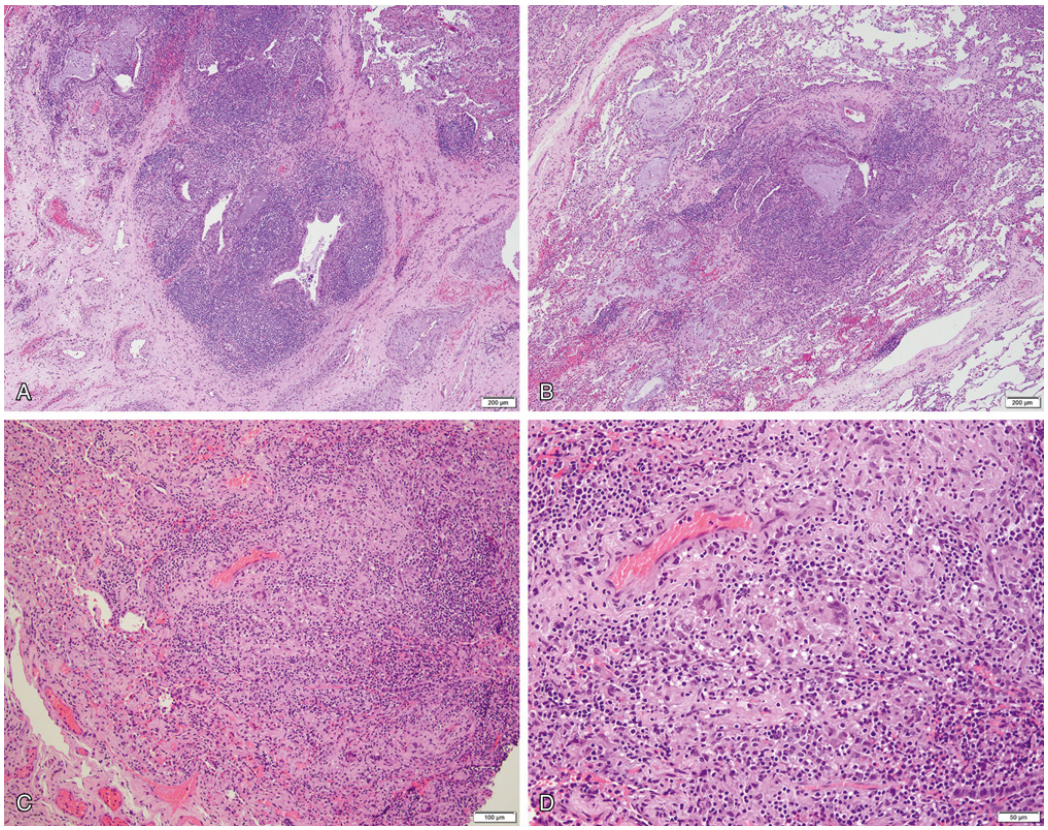

FIGURE 53-5 Lung wedge resection from a patient with a diagnosis of granulomatous lymphocytic interstitial lung disease (GLILD) in a patient with common variable immunodeficiency (CVID) on IV-Ig. **A,** At low power, a patchy peribronchial lymphocytic infiltrate with fibrosis associated with reactive follicles with naked germinal centers. **B,** Postobstructive changes, organizing pneumonia and areas of end-stage lung disease were noted (hematoxylin and eosin [H&E], ×2). **C–D,** Poorly formed granulomata and rare multinucleated giant cells are present (H&E, ×10 and ×40).

Immunologic features include a marked decrease of IgG (two standard deviations below the normal age-adjusted range), a marked decrease of another isotype (IgA or IgM), an absolute decrease in number of naïve B cells and class-switched memory B cells (CD27 positive, IgM negative, IgD negative), and reduced IgM response to polysaccharide immunization. The decreased number of class-switched memory B cells is not unique or distinctive for CVID because it has been described in other PIDs, including X-linked HIGM syndrome, Wiskott-Aldrich syndrome (WAS), X-linked lymphoproliferative disease, idiopathic CD4 lymphopenia, chronic granulomatous disease, and, more recently, phosphatidylinositol 3-kinase (PI3K)-δ deficiency. An increase in transitional immature B cells (CD10 positive, CD38 high, IgM high) is often present in peripheral blood; a more mature population with CD21 low/CD38 low B cells is expanded in CVID, as well as in SLE.[56] The increase in transitional immature B cells is also a striking feature of PI3K-δ immunodeficiency, and it is of interest that several of the patients with this mutation were originally diagnosed as CVID; it is, therefore, tempting to speculate that this particular subset of patients may indeed carry these mutations. In a subset of patients with granulomatous disease and splenomegaly, profound alteration of T-cell compartments is present, with low naïve CD4-positive T cells with an inverted CD4:CD8 ratio and T-cell activation markers[57]; also, low Tregs have been described in patients with more severe immunodeficiency, granulomatous disease, splenomegaly, and cytopenia. This latter phenomenon may account for the presence of autoreactive B cells (CD21 low/CD38 low); it is also of interest that a similar population is present in patients with haploinsufficiency for

CTLA-4, and we can speculate that a subset of patients diagnosed with enteropathy and CVID may carry this genetic defect.

PI3K-Related Immunodeficiencies

Primary immunodeficiencies caused by hyperactivation of the phosphatidylinositol 3-kinase (PI3K) signaling pathway were recently described either as heterozygous gain-of-function mutations in the *PIK3CD* gene encoding p110δ, the leukocyte-restricted catalytic subunit, (APDS1),[58-61] or involving p85α, one of the regulatory subunits that regulates the stability of p110 cellular localization, and function of class IA PI3K (APDS2).[62-65] Engagement of a variety of receptors (integrins, tyrosine kinase, B cells and T cells, cytokine, and G-protein) and other stimuli leads to the production of second-messenger phosphatidylinositol (3,4,5) triphosphates (PIP3) by PI3K kinase activity. These lipids serve as docking sites for proteins with a pleckstrin homology domain, including AKT and its upstream activator, PDK1. AKT plays a central role in proliferation, growth, survival, and metabolism in many cell types. PI3K signaling plays an important role in stages of B-cell and T-cell development, differentiation, function, and homeostasis.

With WES and retargeted Sanger sequencing, mutations were identified in different domains of the PI3K-δ subunit, with some recurring ones (hotspots) among different family members. Modeling of the mutations and functional studies confirmed the hyperactivation of PI3K function leading to sustained AKT/mTOR signaling.

Patients carrying PI3K-δ gain-of-function mutations (APDS1) present, often in childhood, with recurrent sinopulmonary

infections; chronic CMV and EBV viremia; lymphadenopathy; lymphoid proliferation with nodular lymphoid hyperplasia involving respiratory and gastrointestinal systems; and increased lymphoma susceptibility, often EBV-associated.[58-61,66,67]

Some of these patients were initially diagnosed with CVID based on their clinical presentation and immunologic findings. In vivo analysis of their B-cell and T-cell populations revealed normal B-cell numbers, but with a decrease or absence of memory B cells (CD27 positive) and an increased number of transitional/immature B cells (CD10 positive, CD38 high, IgM high) with IgM and CD5 expression as seen in naïve B cells. Bone marrow evaluation reveals lymphocytosis with increased B-cell precursors (hematogones) with evidence of maturation arrest by flow cytometry analysis (**Fig. 53-6**). CD10-positive early-through-transitional hematogones are markedly increased with severely decreased to absent CD10-negative mature B-cells because of impaired class-switch recombination. These findings may raise concern for B-lymphoblastic leukemia. Immunoglobulin levels were variable (IgG), but usually high for IgM with low IgA; falling levels of IgG were observed over time in some patients. These observations were confirmed by in vitro studies where the B-cell proliferation was within normal limits, but the cells have impaired immunoglobulin production (defects in CSR). Interestingly, these findings were also mirrored in the sequential lymph nodes that we obtained from some of these patients, with a progressively increasing number of IgM-positive cells and a decline of IgG and IgA (**Fig. 53-7**). In vivo analysis of the T-cell compartment revealed progressive CD4-positive T-cell lymphopenia and normal-to-high CD8-positive T cells, with an inverted CD4:CD8

ratio and greatly reduced naïve and central memory T cells with a corresponding increase in effector memory (CD45RA negative/CCR7 negative) T cells and terminally differentiated effector memory T cells (TEMRA, CD45RA positive) with a senescent phenotype, particularly in the CD8 subset, which may account for their chronic CMV and EBV viremia.[59]

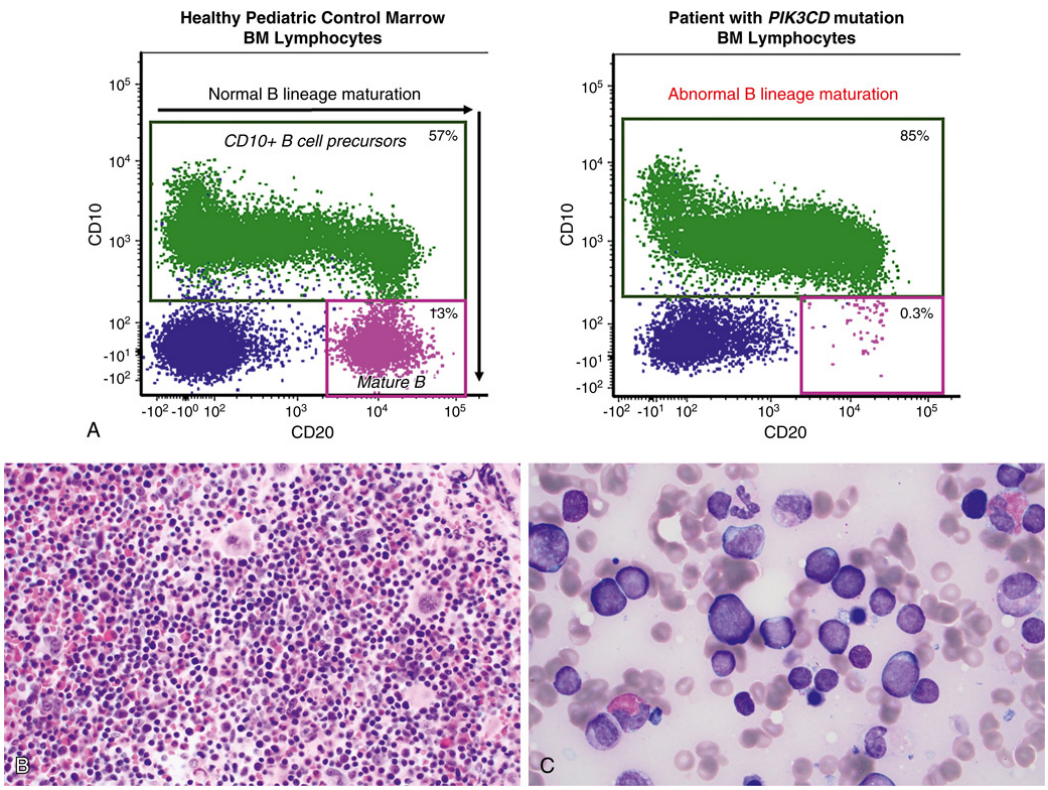

FIGURE 53-6 Hematogone hyperplasia with maturation block in PI3KCD immune deficiency (APDS1). **A,** Flow cytometry analysis of the PI3KCD marrow in comparison to a healthy pediatric control shows markedly abnormal B-cell maturation in the PIK3CD marrow characterized by increased early and transitional CD10 positive immature B-cells with a maturation block, resulting in near complete absence of mature B-cells (CD20 positive and CD10 negative). **B,** Bone marrow biopsy from a pediatric patient shows hypercellular marrow with lymphocytosis (hemotoxylin and eosin [H&E], ×500). **C,** Aspirate smear Wright-Giemsa stain.

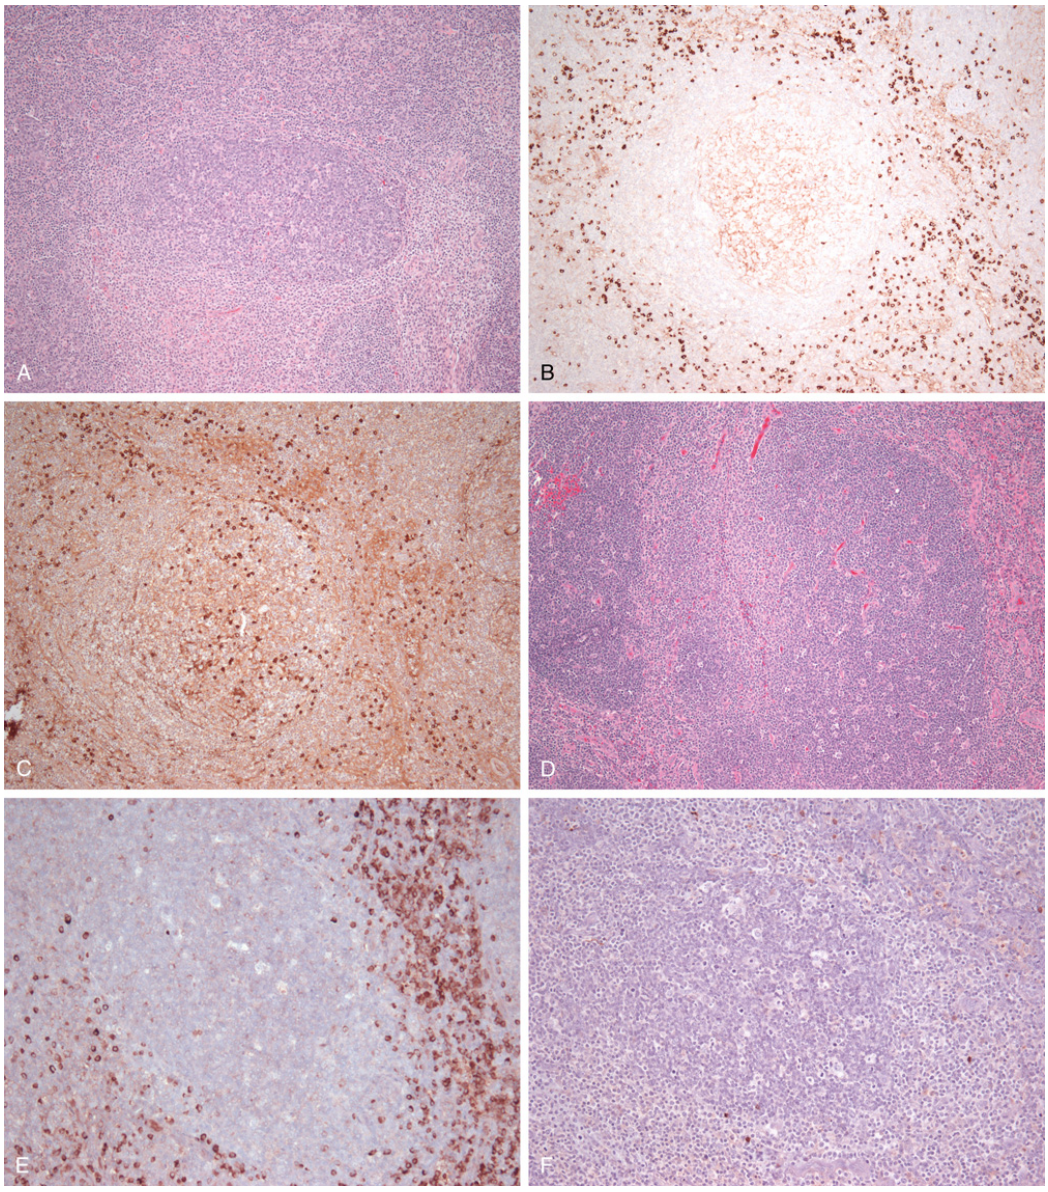

FIGURE 53-7 Lymph node biopsies from a patient with PI3KCD immune deficiency (APDS1). **A,** Low-power view showing typical features with "naked" reactive germinal centers and prominent monocytoid B-cell reaction. **B,** Numerous IgM-positive cells are in the parafollicular areas, and IgG-positive cells are also present within the germinal center **(C).**

Subsequent biopsy (6-year interval) shows similar morphologic features, with large expanded naked germinal centers **(D)** surrounded by numerous IgM-positive cells **(E),** and extremely few IgG-positive cells **(F),** consistent with the serum immunoglobulin levels, simulating a hyper IgM syndrome.

Multiple and sequential lymph node biopsies from several members of different families with a gain-of-function mutation of *PIK3CD* were reviewed. Often these patients had prominent lymphadenopathy involving central and peripheral lymph nodes with compression of the airways in some patients. Lymph nodes showed similar features consisting of an atypical follicular hyperplasia with prominent naked germinal centers often with ill-defined outlines; in addition, a prominent monocytoid B-cell hyperplasia was almost invariably present (see **Fig. 53-7**). In some cases, the overall features resembled CMV lymphadenitis, and in some of these cases CMV infected cells were indeed present; however, in contrast to other cases of CMV lymphadenitis, the mantles were extremely diminished to absent. In some cases, the monocytoid B-cell reaction was more extensive, raising the possibility of involvement by nodal marginal zone lymphoma. However, most cases that were studied by immunoglobulin and T-cell receptor (TCR) gene rearrangements were polyclonal or oligoclonal. EBV, when present by in situ hybridization, was limited to a relatively small number of cells in these otherwise reactive lymph nodes. Plasma cells and plasmacytoid cells are easily identified in the medullary cords and parafollicular areas; in sequential cases over the course of several years, the IgG-

positive cells decline in number, whereas the IgM-positive cells increase (see **Fig. 53-7**).[59] Another striking feature was the expansion of CD279-positive and CD57-positive cells in the T-cell areas consistent with the accumulation of terminally differentiated senescent T cells identified also in the peripheral blood.

In addition, these patients show prominent nodular lymphoid hyperplasia involving the respiratory and gastrointestinal tracts with prominent proliferation of B cells and T cells, often with germinal center formation. The degree of nodular lymphoid hyperplasia at the ileocecal junction can be quite pronounced and lead to intussusception (**Fig. 53-8**).

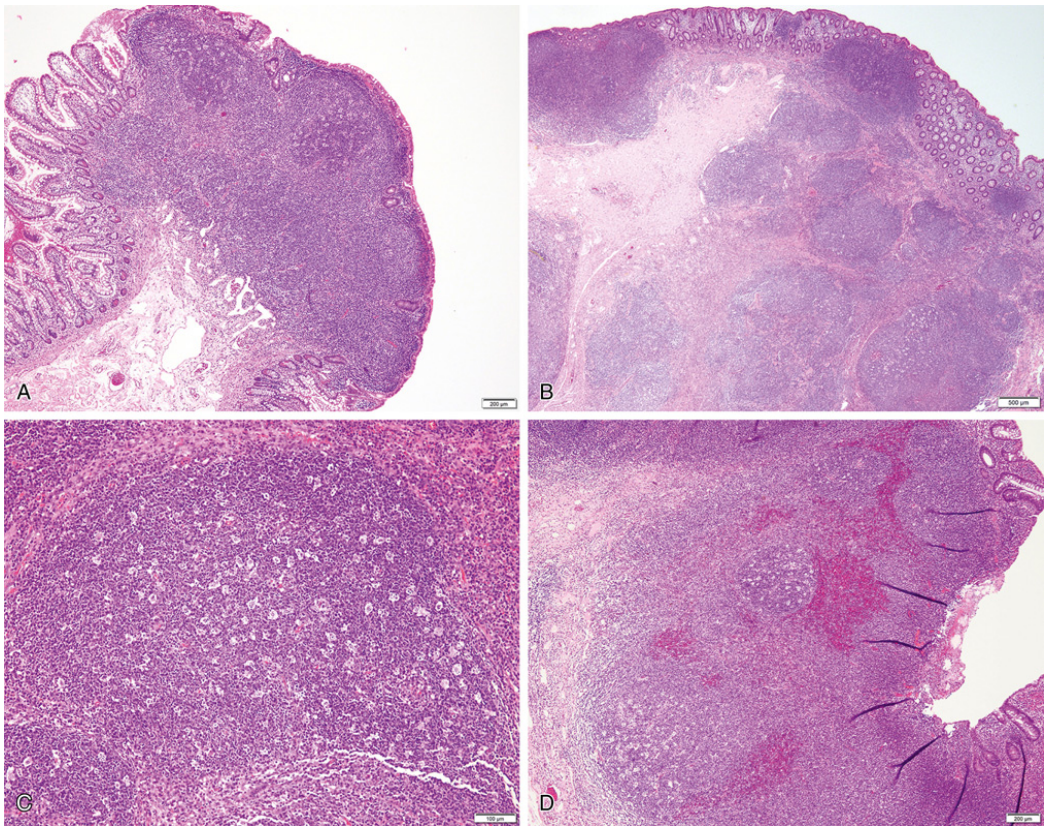

FIGURE 53-8 Ileocecal resection caused by intussusception from a patient with PI3KCD (APDS1). **A,** Prominent lymphoid infiltrate with naked germinal centers and monocytoid reaction adjacent to small intestine, consistent with exuberant Peyer's patches. **B,** Lymphoid proliferation with a nodular growth pattern and fibrosis involving the cecum. **C,** Reactive naked germinal centers are prominent. **D,** Similar features are also noted in the ulcerated areas. Lymph nodes from the ileocecal resection showed reactive changes as often seen in these patients.

APDS1 patients are also at risk of developing classic Hodgkin lymphoma (nodular sclerosis, EBV positive) and non-Hodgkin

lymphoma, diffuse large B-cell lymphoma, and other EBV-positive and non-EBV–associated lymphomas.[59] One family had extensive involvement of the gastrointestinal tract by MALT lymphoma.[60]

With a similar approach (WES and Sanger retargeted), a homozygous mutation (G to A codon 298) with a premature stop codon of the p85α regulatory subunit of the *PIK3R1* gene was originally described in a female patient with IBD and no B cells with a developmental block at the very early B-cell precursors.[68] More recently, heterozygous splice site gain-of-function mutations involving the p85α regulatory subunit of the *PIK3R1* gene, leading to a shortened protein lacking inhibitory activity, have been described in several families.[62,64,65,69] Sequential lymph node biopsies from one patient with a gain-of-function mutation of the *PIK3R1* gene (unpublished) revealed similar changes as described in the *PIK3CD* patients with prominent atypical follicular hyperplasia and monocytoid B-cell reaction with no evidence of CMV- or EBV-infected cells; similar findings were also reported in a tonsil.[65,69]

Agammaglobulinemia

The most severe form of reduction of all serum Ig isotypes is found in agammaglobulinemia due to mutations that prevent signaling through the B-cell receptor, resulting in a block of B-cell differentiation and lack of mature B cells. The majority of these rare patients carries a mutation in the genes encoding Bruton's tyrosine kinase (BTK) (XL) (85%), adaptor BLNK (AR) (5%–7%), and in the pre-BCR chains (μ heavy chain, λ5 surrogate light chain) and Igα surrogate receptor (5%–7%).[70]

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA) is a rare PID with an estimated minimal birth rate of 1 in 379,000 averaged over a 10-year period; as predicted, an increased susceptibility to infections is the most common initial clinical manifestation (86%). It is of interest that diagnosis is frequently delayed even in patients with a positive family history; regardless, nearly all patients become symptomatic before age 5 years. Most infections are because of encapsulated bacteria involving the upper and lower respiratory tract, but viral infections are also reported.[71] These patients have hypoplastic to absent tonsils, adenoids, and lymph nodes.

X-Linked Lymphoproliferative Disorder

Classic X-linked lymphoproliferative disorder (XLP1) is a prototypical PID associated with development of EBV-related lymphoproliferative processes caused by the inability to handle EBV infection. David Purtilo and colleagues described it in 1975 based on a study from a single generation of the Duncan family.[72] XLP1 is caused by a mutation in the *SH2D1A* gene, which encodes the signaling lymphocyte activation molecule (SLAM)-associated protein (SAP), while mutations in the *BIRC4* gene, encoding the X-linked inhibitor of apoptosis protein (XIAP), cause XLP2. There is a clinical overlap between the two genetic defects. It is a rare immunodeficiency with a prevalence of approximately 1 per 1 million males for XLP1 and 1 per 5 million males for XLP2. SAP is expressed in T cells and NK cells and is required for cytotoxicity of B cells.

In general, in affected male patients, EBV infection leads to an exaggerated and often fatal infectious mononucleosis–like syndrome with lymphadenopathy caused by polyclonal B-cell and CD8-positive

T-cell expansions, often with involvement of liver, spleen, and bone marrow, leading to hemophagocytic lymphohistiocytosis (HLH) and bone marrow failure. Other symptoms include B-cell lymphoma and dysgammaglobulinemia. However, hypogammaglobulinemia and lymphomas can also develop independently of EBV infection in seronegative individuals and the underlying mechanism is poorly understood, but it implies that EBV is not necessary for the development of all clinical features. In rare instances, aplastic anemia, vasculitis, and lymphomatoid granulomatosis have been described in these patients.

From an immunologic standpoint, these patients have a reduced number of memory B cells, several cellular defects involving effector functions of CD8-positive/CD4-positive T cells and NK cells, and lack NKT cells.[73] The critical role of SAP in these different cellular subsets has been elucidated, with multiple elegant studies showing that the increased susceptibility to EBV infections is linked to decreased cytotoxicity of SAP-deficient CD8-positive T cells and NK cells, whereas the development of hypogammaglobulinemia is most likely caused by an intrinsic defect of CD4-positive T cells. Ninety-five percent of EBV-specific CTLs are indeed in the SAP-positive subset of CD8 T cells, whereas CMV and other virus-specific CTLs are equally present in SAP-positive and SAP-negative CD8 T cells; hence, the response to other viruses is not affected in XLP patients. Moreover, the lack of SAP in CD8-positive T cells also has an inhibitory effect by limiting the interaction with B cells through a defect in synapse formation and preventing the clearance of EBV-infected B cells.[74] The reduced cytotoxicity of SAP-deficient NK cells mediated through the 2B4 (CD244) receptor, part of the Ig

superfamily together with SLAM, also plays a role in the poor handling of EBV infection, without affecting other NK-cell functions that are mediated through different receptors and do not require SAP as a second messenger. It is known that patients who lack NK cells or have severe functional NK-cell defects are susceptible to recurrent human herpesvirus infections with CMV, varicella-zoster virus (VZV), and EBV.[75] The absence/deficiency of NKT cells may also contribute to the susceptibility to EBV and the development of lymphoma, because other PIDs with similar clinical features caused by mutations involving *CD27, ITK, BIRC4,* and *CORO1A* also have low numbers of NKT cells. Lastly, the defective humoral immunity with subsequent development of hypogammaglobulinemia caused by poor antibody formation, and deficit in memory B cells has been shown to be related to intrinsic defects of CD4-positive T cells and impaired formation of follicular T-helper cells. To this extent, review of the pathology material from the XLP registry has revealed that some of these patients fail to form normal germinal centers, although some are present in gastrointestinal biopsies.

XLP2 is less common, with only about 70 cases reported since 2006. The main clinical features are increased susceptibility to EBV-HLH; recurrent splenomegaly; and IBD with Crohn's-like features. XLP2 is considered one of the underlying causes of IBD in infancy. XIAP consists of antiapoptotic molecules but is also involved in innate immunity and inflammation (as a negative regulator through the NOD pathway).[76]

Several other diseases with immune dysregulation, such as familial HLH syndromes leading to increased susceptibility of EBV infections, chronic active EBV, and EBV-driven lymphoproliferative

disorders/lymphoma, are discussed in the chapters related to EBV (**Chapters 28** and **29**).

Defects that Affect Homeostasis of The Immune System

The identification of PIDs that, as result of a single gene defect, give rise to multiple autoimmune phenomena has helped in understanding the immune dysregulation caused by a decreased ability in differentiating between self and foreign antigens. These disorders have offered the opportunity to better understand regulatory T-cell function both centrally and peripherally, how they develop, and how they maintain homeostasis.

Autoimmune polyendocrinopathy-candidiasis ectodermal dysplasia (APECED) is a monogenic autoimmune disease caused by biallelic LOF mutation in the autoimmune regulator *AIRE* gene, a transcription factor that promotes expression of tissue-restricted antigens[77] and that is expressed in a subset of medullary TECs.[78] It participates in the negative selection of self-reactive T cells and generation of self-antigen specific regulatory Tregs. AIRE deficiency is also associated with impaired B tolerance, resulting in the production of autoantibodies.[77] It has been shown that several patients have diminished and defective Tregs.[79]

APECED is clinically defined by chronic mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency; however, it is a multisystem autoimmune disease involving several endocrine and nonendocrine organs.[80,81]

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX) is a rare syndrome that presents with severe

autoimmune enteropathy, eczema, early-onset endocrinopathy, and other autoimmune diseases. It is caused by mutation in the forkhead box protein P3 *(FOXP3)* gene. Allergic manifestations with eczema and food allergies are common with elevated IgE, hypereosinophilia, and TH2-skewing.[82] The mouse model—*Scurfy* mice, in which the lack of Tregs leads to lethal lymphoproliferative disorder with multiorgan infiltration—and IPEX patients share many similarities. Genotype/phenotype correlation has been demonstrated with some of the *FOXP3* mutations that maintain a near-normal protein expression and are associated with a milder clinical phenotype with normal number of Tregs, but with altered functionality.[83] Other genetic mutations may give rise to an IPEX-like syndrome including CD25 (IL2Ralpha) deficiency and STAT5b deficiency; in addition, some patients also with gain-of-function *STAT1* mutations have been reported.[84-86]

Autosomal Dominant Immune Dysregulation Syndrome With Heterozygous Germline Mutations of Cytotoxic T Lymphocyte–Associated Protein 4

This disease has been recently characterized.[87,88] Heterozygous mutations in CTLA4 lead to T-cell impairment with immune dysregulation with later onset compared with IPEX, and incomplete penetrance. Several of these patients had a diagnosis of CVID caused by hypogammaglobulinemia, deficit in antibody production, and expansion of autoreactive B cells. Tregs constitutively express the inhibitory receptor CTLA4, which is an essential part of their suppressive functions. Upon antigen presentation by dendritic cells (or other specialized AP cells) in the presence of T-cell receptor,

costimulatory molecule CD28 mediates T-cell effector function, T-cell activation, and generation of memory T cells, and provides helper function to B cells and antibody production. The inhibitory signals of these events are mediated by CTLA4. Both receptors share the same ligands CD80/CD86; it has been shown that CTLA4 not only recycles from the surface to the cytoplasm of T cells, where it can either be recycled to the surface or digested, but also has the ability to remove the ligands (CD80 and CD86) from the antigen-presenting cells (APCs) via transendocytosis.[89] Both mechanisms offer a way to regulate the availability of ligands and subsequently enhance or reduce T-cell activation and proliferation.

Patients present with recurrent respiratory tract infections, hypogammaglobulinemia, autoimmune cytopenias (thrombocytopenia resembling immune/idiopathic thrombocytopenic purpura [ITP], autoimmune hemolytic anemia), autoimmune enteropathy, and CNS lesions. Lymphadenopathy is present in about one-third of patients and in conjunction with cytopenias can prompt consideration of autoimmune lymphoproliferative syndrome (ALPS). Histologically, there are lymphocytic infiltrates involving the gastrointestinal tract with evidence of enterocolitis consistent with lymphocytic or neutrophilic (cryptitis) colitis, as well as lymphoid hyperplasia with a mixture of B cells and T cells; a full clinical spectrum of severity corresponding to underlying histology (not infectious) similar to the enterocolitis in patients treated with anti-CTLA4 antibody is observed.[90] Another distinguishing feature in these patients is the inflammatory infiltrate involving the CNS with supratentorial and infratentorial lesions, occasionally involving the brainstem or spine (**Fig. 53-9**). It is of

interest that the degree of involvement by MRI does not correlate with severity of clinical symptoms.[91] Histologically, the infiltrate is either lymphohistiocytic with scattered plasma cells or mostly lymphoplasmacytic. There is no necrosis, granulomata, or tissue destruction; by immunophenotype, the majority of lymphocytes are T cells with a predominance of CD4-positive cells, plasma cells are often polyclonal, and in only one patient was there light chain restriction. Histology of the lymph node is more varied; in some cases follicular hyperplasia is present, and only one case showed an atypical T-cell proliferation not clonal in nature, but composed predominantly of CD8-positive T cells. One patient has been described with EBV-positive classic Hodgkin lymphoma.[87]

From an immunologic standpoint, quantitative deficiencies of CTLA4 are observed, leading to altered homeostasis with lymphopenia, but pronounced autoimmune phenomena with lymphocytic infiltrates in various organs. A progressive B-cell lymphopenia is also noted, with an increase of autoreactive B cells.[87,88]

There are several patterns of bone marrow pathology in CTLA4 deficiency. A subset of patients develops pancytopenia and has hypocellular marrow with prominent atypical lymphoid aggregates composed largely of T-cells with markedly decreased to absent B-cells (**Fig. 53-10A–B**). The T cells in the lymphoid aggregates are predominantly CD4 positive, while the T-cells scattered interstitially throughout the marrow are predominantly CD8 positive (**Fig. 53-10C–F**). In some patients, the marrow cellularity may be so low (<20%) that it raises concern for aplastic anemia. Other CTLA4 patients have hypercellular marrows with massive T-cell infiltration

(**Fig. 53-11**), while a subset with thrombocytopenia and autoimmune hemolytic anemia may have hypercellular marrows with increased megakaryocytes and erythropoiesis, which may resemble ITP marrow (**Fig. 53-11**).

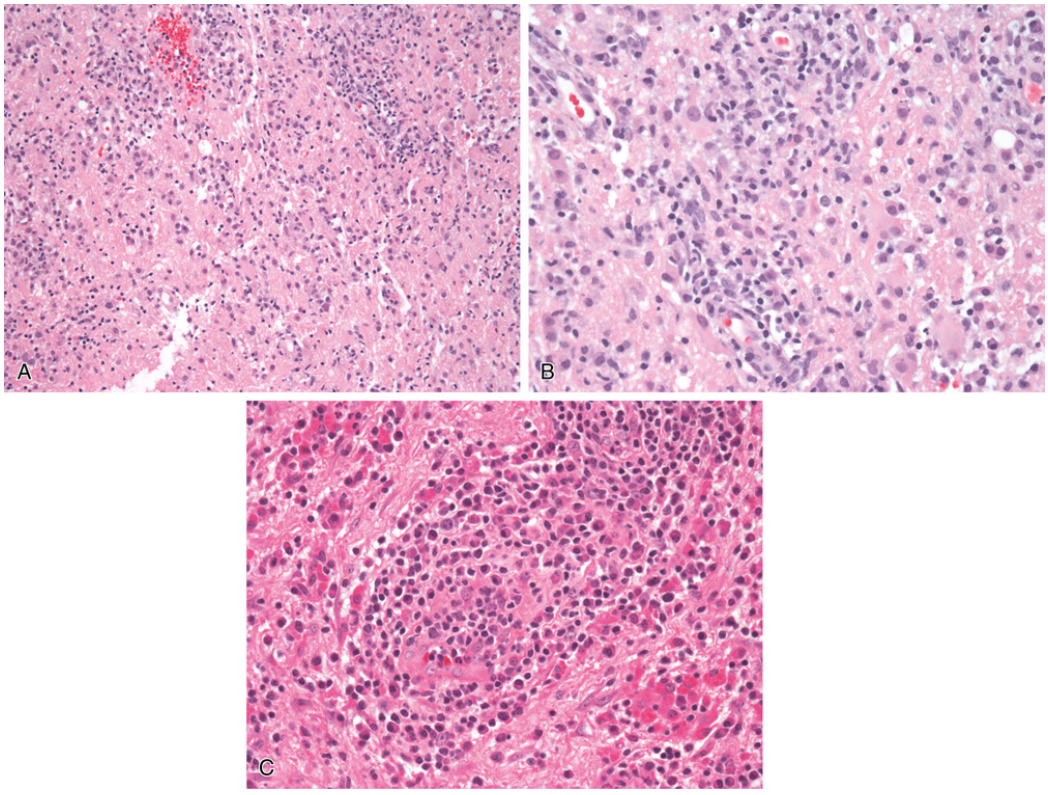

FIGURE 53-9 Brain biopsies from two different patients with CTLA4 deficiency.A–B, Lymphohistiocytic infiltrates involving the white matter with isolated plasma cells are shown. The lymphocytes are predominantly T cells. **C,** A dense plasmacytic perivascular infiltrate extending into the surrounding brain parenchyma; the plasma cells are polyclonal.

Autoimmune Lymphoproliferative Syndrome

ALPS, also known as Canale-Smith syndrome,[92] is a genetic disorder characterized by lymphoid proliferation caused by impaired apoptosis leading to the accumulation of TCRαβ positive CD4/CD8-double negative T (DNT) cells, both circulating and within lymph nodes; splenomegaly; multiple cytopenias; and increased risk for developing B-cell lymphomas of both Hodgkin and non-Hodgkin type.[93] In ALPS, lymphocyte homeostasis is disrupted because of defects in the FAS-mediated apoptotic pathway; the majority of patients have deleterious heterozygous germline mutations involving the *FAS* gene or, less commonly, *FASLG* or *CASP10*. Somatic mutations involving the *FAS* gene have also been described.[94] An international workshop revised the diagnostic criteria for ALPS and proposed to divide them into two required criteria and six accessory criteria, further subdivided into primary and secondary (**Box 53-1**).[95] For a definitive diagnosis of ALPS, both required criteria have to be met, as well as one of the primary accessory criteria; a diagnosis of probable ALPS is based on both required criteria and one of the secondary accessory criteria. The two required criteria are the presence of noninfectious, nonmalignant chronic lymphadenopathy (>6 months) or splenomegaly and an elevated TCRαβ-positive DNT cells (≥1.5% of total lymphocyte count or 2.5% of CD3-positive lymphocytes in the setting of a normal or elevated lymphocyte count); the two primary accessory criteria are defective apoptosis and presence of germline or somatic mutations in *FAS, FASLG,* or *CASP10*. The presence of typical morphologic and immunophenotypic findings represents one of the secondary accessory criteria. A history of other autoimmune disorders like

Hashimoto thyroiditis or type 1 diabetes can led to the diagnosis when considered together with waxing or waning lymphadenopathy or lymphocytosis. Note that lymphadenopathy and splenomegaly often resolve once patients reach adolescence or adulthood.

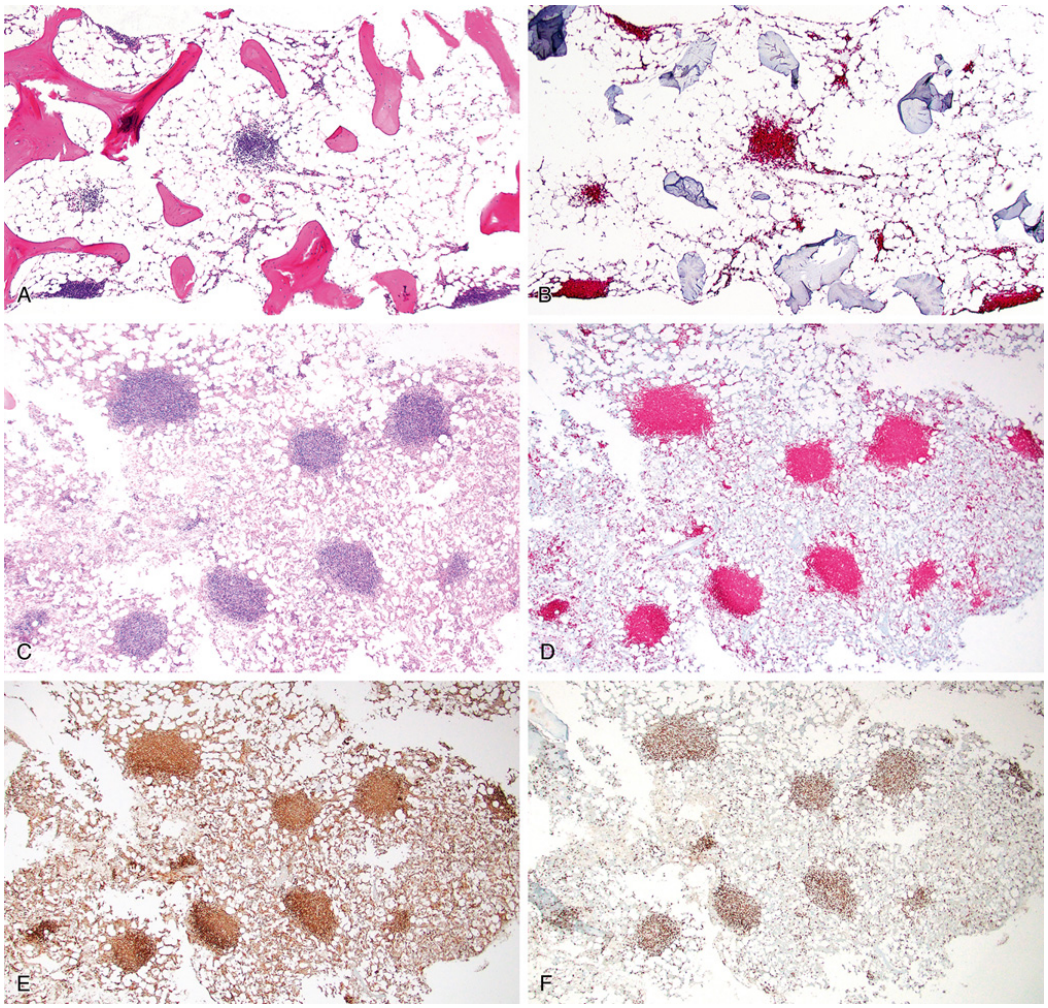

FIGURE 53-10 Bone marrow pathology in CTLA4 deficiency. **A–B,** Hypocellular marrow with atypical T-cell aggregates. Marrow from an 18-year-old male with pancytopenia and CTLA4 deficiency. The marrow was hypocellular for age with multiple atypical lymphoid aggregates **(A)**, which were positive for CD3 with T cells **(B)**. B-lineage cells were notably absent, demonstrated by CD79a (not shown). Karyotype was normal and TCRG PRC revealed polyclonal T cells. **C,** Marrow from a 44-year-old male with CTLA4

deficiency and marked pancytopenia. The marrow was hypercellular with a prominent nodular infiltrate composed largely of T cells **(D)** that were a mixture of CD4 positive cells **(E)** and CD8 positive cells **(F)**. B cells were decreased. Karyotype was normal and TRG PCR was polyclonal.

Recent studies on the natural history of ALPS based on long-term follow-up of over 200 patients showed a male predominance, a median age at onset of symptoms of approximately 3 years, and a *FAS* mutation in the intracellular domain in 70% to 83% of patients; in contrast, somatic *FAS* mutations more frequently occurred in the extracellular domain. In addition, only a 60% penetrance was found among family members carrying the same heterozygous gene mutation, indicating that other genetic differences or modifiers may exist. As expected, nearly all symptomatic patients had chronic adenopathy and splenomegaly. Laboratory findings revealed a median percentage of DNT cells of 5.9%; increased concentrations of vitamin B_{12}, IL10, and soluble FASL, all known biomarkers that are usually present in ALPS; hypergammaglobulinemia; and autoimmune cytopenias in 61% to 69% of patients. Risk for sepsis was higher in patients who underwent splenectomy at an earlier age.[96-98]

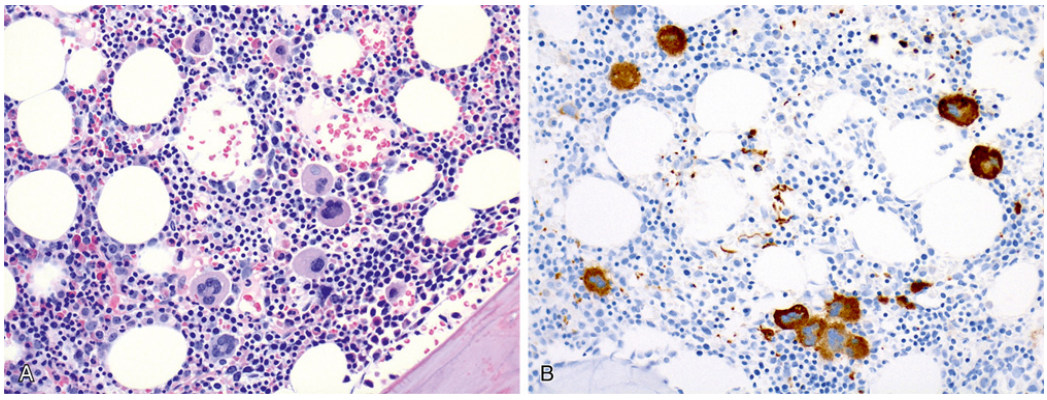

FIGURE 53-11 Bone marrow from a patient with CTLA4 presenting as immune/idiopathic thrombocytopenic purpura (ITP). **A,** Mild megakaryocytic hyperplasia (**B,** CD61 immunostain) in a bone marrow biopsy from an 8-year-old boy who presented with thrombocytopenia and high immature platelet fraction (accompanied by absolute neutropenia and mild anemia), whose initial response to IVIg suggested ITP.

Box 53-1 Autoimmune Lymphoproliferative Syndrome (ALPS) Diagnostic Criteria (2009)

Required

Chronic (>6 months), nonmalignant, noninfectious lymphadenopathy or splenomegaly
Elevated CD3-positive TCRαβ-positive CD4-CD8–double-negative T cells (≥1.5% of the total lymphocytes or 2.5% of

the CD3-positive lymphocytes in the setting of normal or elevated lymphocyte counts)

Accessory

Primary

Defective lymphocyte apoptosis
Pathogenic mutations in *FAS, FASLG,* and *CASP10*

Secondary

Elevated biomarkers (sFASL, IL10, vitamin B_{12}, IL18)
Typical immunohistologic findings
Autoimmune cytopenias and increased IgG
Family history

For a definitive diagnosis: Both required criteria plus one primary accessory criterion. For a probable diagnosis: Both required criteria plus one secondary criterion.

Lymph node biopsies in ALPS type 1A (*FAS* mutations) patients reveal a preserved architecture, with often widely spaced secondary B follicles (some hyperplastic and some regressed) and a prominent paracortical hyperplasia characterized by a proliferation of lymphoid cells varying in cell size with more open chromatin and lacking the typical features of paracortical hyperplasia with small lymphocytes and condensed chromatin interspersed with macrophages and dendritic cells. Plasmacytosis in the medullary cords is also often present. A DNT cell population can be identified with immunohistochemical staining in a subset of cases, but flow cytometry is more sensitive and more accurate (**Fig. 53-12**).

Abundant S100-positive dendritic cells are also present within the expanded paracortex. In a subset of patients, changes consistent with sinus histiocytosis with massive lymphadenopathy (SHML), also known as Rosai-Dorfman disease, can be observed either as focal or diffuse involvement. Because of the overlapping symptomatology between SHML and ALPS, the latter possibility should be excluded on clinical and immunologic grounds.[99] In ALPS patients, there is also an increased risk for lymphomas, which include both Hodgkin and non-Hodgkin B-cell lymphomas. A subset of these can be associated with EBV, particularly mixed cellularity classic Hodgkin lymphoma and Burkitt lymphoma.[96] Interestingly, some asymptomatic family members may also develop lymphoma, but it is unclear whether this is related to the underlying *FAS* mutation.

Defects in Synapse Formation and Crosstalk Between Antigen-Presenting Cells and T Cells

Wiskott-Aldrich Syndrome

WAS is an X-linked PID characterized by eczema, thrombocytopenia with a decreased mean platelet volume, severe and often recurrent infections, and autoimmune disorders.[100] Prevalence in the United States is approximately 1 to 4 cases per 1,000,000 live male births and 1.2% of patients with identified primary immune defects.[101]

The *WAS* gene is located at Xp11.22-p11.23; the WAS protein (WASp) is involved in actin polymerization and plays a central role in TCR signaling to full T-cell activation, cytoskeletal remodeling, synapse formation, and migration. Mutations have been described along the entire *WAS* gene. The WASp family comprises eight

members of actin regulatory proteins with different functions in various tissues[102,103]; WASp is exclusively present in hematopoietic cells. Variations in WASp expression or function correlate with the clinical spectrum, ranging from classic WAS with no protein expression to phenotypic variation of X-linked thrombocytopenia (XLT) with partial expression of the protein and X-linked neutropenia (XLN), caused by activating mutations. Female carriers are asymptomatic, with extreme rare symptomatic cases caused by deleterious mutations on the paternally derived X chromosome and non-random inactivation of the maternally derived X chromosome. When the mutation results in lack of WASp expression, the classical syndrome occurs. Spontaneous chimerism caused by genetic reversion, which may confer a selective advantage, has been observed in about 11% of patients, but the clinical significance of this finding is unclear.[104] A similar phenomenon has been observed in numerous other PIDs is not unique to WAS.

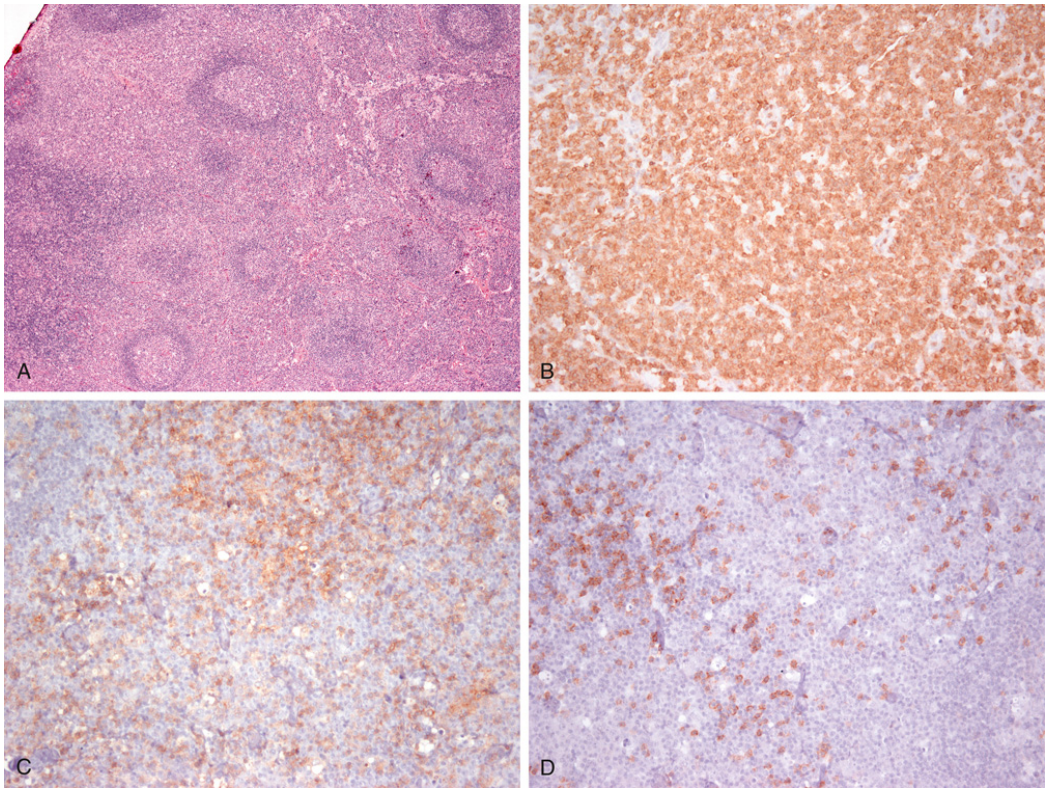

FIGURE 53-12 Lymph node biopsy from a patient with autoimmune lymphoproliferative syndrome (ALPS) type 1A (*FAS* mutations in the intracellular death domain). **A,** Hematoxylin and eosin (H&E) shows an atypical paracortical hyperplasia. **B,** CD3-positive T cells are shown. The majority lack CD4 **(C)** and CD8 **(D)** expression, consistent with double-negative T cells, typically seen in ALPS.

Clinically, patients present with skin rash (eczema) and bleeding (80%), such as petechiae and ecchymoses. Past medical history may also include mucosal or intracranial bleeding, recurrent sinopulmonary (otitis media, 64%; pneumonia, 25%), viral (herpes simplex virus 1 and 2, VZV, molluscum contagiosum), fungal, and

opportunistic *(P. jirovecii)* infections. Autoimmune phenomena, seen in 40% of patients, include cytopenias (autoimmune hemolytic anemia in 14%), vasculitis (13%), IBD, arthritis (10%), and renal disease (IgA nephropathy, 12%). WAS patients are also at risk for developing lymphomas (13%) at a mean age of 9.5 years. EBV-positive non-Hodgkin lymphomas occur more frequently than classic Hodgkin lymphoma, and Burkitt lymphoma, lymphoblastic leukemia/lymphoma, and diffuse large B-cell lymphoma/lymphomatoid granulomatosis have been described in WAS patients. They can also develop myeloid disorders.[101]

Flow-cytometric analysis with quantification of intracytoplasmic WASp expression is used as a screening tool in suspected cases and allows for identification of various disease states.

Sequencing of the entire *WAS* gene (exons, intron and exon boundaries, and upstream regulatory regions) is recommended if diagnosis needs further confirmation; targeted sequencing is usually done in cases with family history and known mutations. Sequencing also has been used in the context of prenatal diagnosis in at-risk couples.

Laboratory findings confirm that all arms of the immune system are affected: adaptive, humoral, and innate. Quantitative immunoglobulins reveal variable IgM, with normal to high IgA and elevated IgG and IgE. Abnormal isohemagglutinin titers and diminished vaccine responses are present. Analysis of lymphocyte subsets reveals T-cell lymphopenia (lymphocyte count less than 1000/μL) with an abnormal response to mitogen. T-cell defects also lead to impaired antibody production by B cells, but intrinsic defects in B cells have also been described with hyper-responsiveness and

autoantibody production.[105] Cytotoxic T cells and NK cells are also defective in their killing of targets because of the inefficient polarization of cytotoxic granules to the cell surface and inability to form synapses. This deficit in cytotoxic activity, in conjunction with the lymphopenia and intrinsic T-cell and B-cell defects, may be ultimately responsible for the inability to clear infectious agents and may contribute to the development of B-cell lymphomas.

Morphologically, in the spleen, depletion of the white pulp with diminished marginal zones and decreased numbers of B cells and T cells has been described.[106] Enlarged lymph nodes are often biopsied to monitor for the possible development of lymphomas; they usually show preserved architecture with prominent reactive secondary B follicles and expanded paracortex with prominent eosinophilia.

Warts, Hypogammaglobulinemia, Infections, and Myelokathexis

Warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome is caused by autosomal dominant mutations in *CXCR4;* this is a rare disorder that can affect both males and females and can also present with either B-cell or T-cell lymphopenia. CXCR4 is a G-protein–coupled transmembrane receptor that is broadly expressed in leukocytes and other cells; its ligand, SDF-1 (CXCL-12), is secreted by many cells except blood cells. Most of the mutations abolish phosphorylation of CXCR4, inhibiting recycling of the receptor and leading to its prolonged activation.[107] Both chemokine and its receptor mediate the mobility and localization of T cells and APCs within secondary lymphoid organs and likely regulate their interaction, and ultimately confer stability to the

T/APC synapses. Myelokathexis, a Greek neologism meaning bone marrow (*myelo*-) retention (-*kathexis*), refers to accumulation of mature neutrophils as they are unable to be released from the marrow. Bone marrow evaluation reveals hypercellularity with granulocytic hyperplasia and a right-shift with an abundance of mature neutrophils (**Fig. 53-13**). In aspirate smears, many of the neutrophils have a distinctive appearance, with pyknotic nuclear segments attached by long, wispy strands of chromatin, sometimes accompanied by cytoplasmic vacuoles (**Fig. 53-13**), though these cells are not seen in circulation. Use of CXCR4 inhibitors ameliorates neutropenia by allowing the release of neutrophils from the marrow.[108] Patients with WHIM syndrome also have a defect in high-affinity antibody maturation, likely because of defective CSR, with decreased antigen-specific memory responses.[109] These patients are also prone to EBV-related lymphomas.

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is a rare autosomal recessively inherited disorder typically manifesting initially around age 2 years as progressive cerebellar degeneration (ataxia), with a later onset of oculocutaneous telangiectasias that first appear on the bulbar conjunctivae, ears, and nose; patients also suffer from defects in both cellular and humoral immunity (with thymic hypoplasia) predisposing them to sinopulmonary infection, and they face an increased risk of lymphoid and nonlymphoid tumors, the former developing earlier in life.[110] AT is caused by biallelic mutations in the *ATM* (ataxia-telangiectasia mutated) gene located on chromosome 11q22.3-23.1, which normally codes for a 350-kDa serine-threonine

kinase, part of the PIK-related protein kinase family. ATM plays an important role in responding to DNA damage, which underlies the increased risk of malignancy in AT patients, and it is important to remember they are also hypersensitive to ionizing radiation: serious and sometimes fatal reactions can result when conventional doses of radiation therapy are used to treat those cancers. AT patients develop clonal T-cell proliferations with recurrent rearrangements involving chromosomes 7 and 14, where the TCR genes reside, that may evolve to T-prolymphocytic leukemia (T-PLL). Interestingly, T-lymphoblastic leukemia (T-ALL) and T-PLL occur less frequently than was previously thought. Acquired somatic mutations of the *ATM* gene are also detected in several lymphoproliferative disorders, including chronic lymphocytic leukemia and mantle cell lymphoma. A review from the French national registry of primary immune deficiencies reported cancer in 24.5% (69 of 279) of AT patients.[111] Of the patients, 38 developed non-Hodgkin lymphoma, mostly of aggressive B-cell type (median age, 9.7 years; 50% EBV positive), while 12 developed Hodgkin lymphoma (median age, 10.6 years; all EBV positive), with 8 patients each developing ALL (median age, 8.3 years, including 4 cases of T-ALL) or carcinoma (median age, 31.4 years; breast, gastric, liver, and thyroid), and 3 with T-PLL (median age, 24.2 years). Myeloid neoplasms are uncommon in AT, and as one would expect, overall survival is shorter in patients with AT who develop cancer.

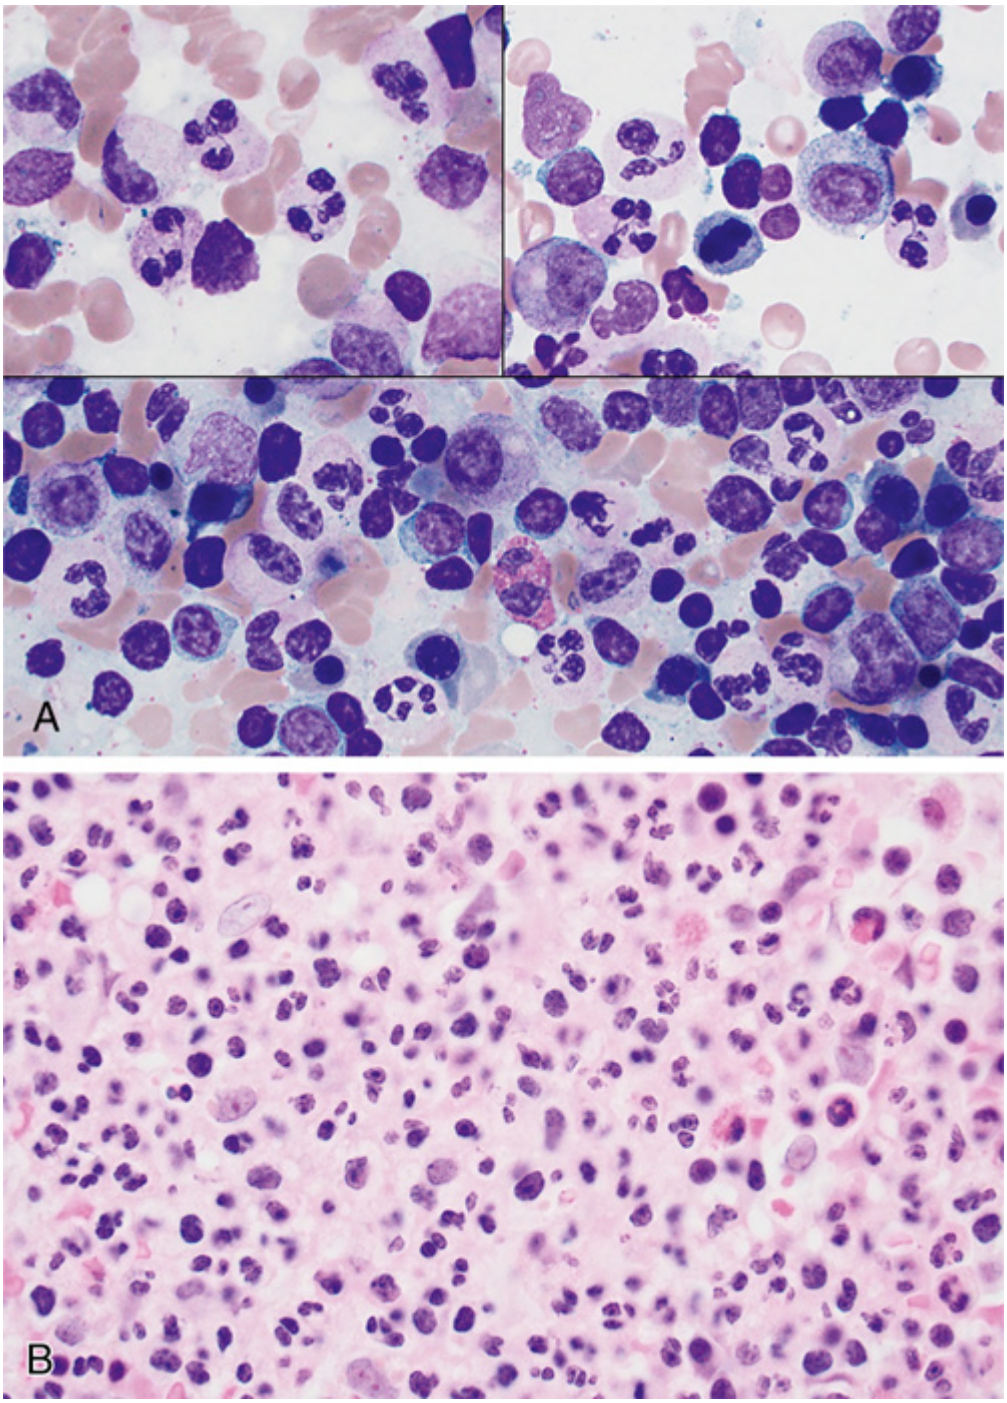

FIGURE 53-13 WHIM and myelokathexis.A, Marrow aspirate from a warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) patient showing a subset of characteristic WHIM neutrophils with pyknotic

nuclear segments attached by thin chromatin strands (×1000, Wright-Giemsa). **B,** Bone marrow biopsy shows markedly hypercellular marrow with right-shifted myeloid hyperplasia and increased mature neutrophils demonstrating myelokathexis (×500, hematoxylin and eosin [H&E]).

Pearls and Pitfalls

- The concept of primary immunodeficiency (PID) has expanded over time and now includes 10 categories: combined immunodeficiencies, combined immunodeficiencies with syndromic features, predominantly antibody deficiencies, diseases of immune dysregulation, congenital defects of phagocytes, defects in intrinsic and innate immunity, autoinflammatory diseases, complement deficiencies, bone marrow failure, and phenocopies of inborn errors of immunity.
- With the use of modern technologies such as whole-exome sequencing (WES) and whole-genome sequencing (WGS), the number of PIDs with identified genetic defects has exploded from just over 100 to 485 in 20 years.
- Age of onset is commonly during but certainly not limited to infancy and early childhood; Common variable immunodeficiency (CVID) is a notable exception.

- The pathology should be interpreted in the context of the clinical presentation, family history, and appropriate immunologic workup.

IATROGENIC IMMUNODEFICIENCY-ASSOCIATED LYMPHOPROLIFERATIVE DISORDERS IN NONTRANSPLANT SETTINGS

Definition

Lymphoproliferative disorders (LPDs) associated with iatrogenic immunodeficiency constitute a spectrum of lymphoid or plasmacytic proliferations, including a major subset that occurs after solid organ or hematopoietic stem cell transplantation (posttransplant lymphoproliferative disorders [PTLDs]). A smaller number of cases occur in other situations, such as in patients with rheumatoid arthritis treated with methotrexate, in young patients with Crohn's

disease treated with tumor necrosis factor-α (TNF-α) antagonists along with antimetabolites, or rarely after some chemotherapeutic agents (other iatrogenic immunodeficiency-associated LPDs [OIIA-LPDs]). Many LPDs are associated with Epstein-Barr virus (EBV). They require further classification because of the great variation in their cytologic composition, degree of destructiveness, immunophenotype, cytogenetic and molecular findings, clinical behavior, and therapeutic approach.[1-7] Cases range from hyperplastic-appearing lesions to others that are indistinguishable from non-Hodgkin or Hodgkin lymphoma in immunocompetent hosts. Even the lymphoma-like cases are separately designated because reducing or discontinuing immunosuppression, when possible, or administering therapy that would be considered inadequate in immunocompetent hosts may lead to resolution.

Classification

The classification of immunodeficiency-associated LPDs is currently controversial (**Box 54-1**). The 2022 International Consensus Classification of Lymphoid Neoplasms (ICC) retains the categories of

immunodeficiency-associated LPDs outlined in the World Health Organization (WHO) Revised 4th ed. classification.[5,8] The ICC classification preserves the category of PTLD because of the extensive literature regarding the clinicopathologic features of PTLD, which include therapeutic strategies that are not necessarily applicable to other immunodeficiency-associated LPDs.[8-18] Clinical guidelines published for managing patients with PTLD, and benchmark surveys about diagnosis, prevention, and treatment of PTLD are neither intended for nor tested in patients with OIIA-LPDs.[17,19] Thus, a proliferation like a diffuse large B-cell lymphoma, not otherwise specified (DLBCL, NOS) occurring in the posttransplant setting is viewed very differently from one occurring in a patient with HIV infection. Aside from the very different clinical settings, with therapeutic implications, biological differences including different prognostic implications have been documented between HIV-associated and PTLD DLBCL-type lesions.[20-22] Though difficult to be certain, Hodgkin type LPDs appear to be more common among the OIIA-LPDs than in the posttransplant setting, where they are very infrequent. In addition, while the diagnosis of PTLD is often made with great confidence, subclassification may be more problematic due in part to B-cell PTLDs forming a spectrum from nondestructive polymorphic proliferations to more destructive but polymorphic proliferations to proliferations that would fulfill the criteria for a conventional lymphoma, even if treatment strategies will differ. There remains a lack of consensus even on whether some of the subclassification matters clinically.[1,4,23] In contrast to this separate designation of PTLD, the proposed WHO 5th ed. includes a broad category of “lymphoid proliferations and lymphomas

associated with immune deficiency and dysregulation" listed under the broader category of "mature B-cell neoplasms," even though some PTLD are of Hodgkin or T-cell type.[24-26] This category includes not only iatrogenic immunodeficiency-associated disorders, but also those associated with primary immunodeficiencies, termed "inborn errors of immunity."[26] The classification then uses a three-part unifying nomenclature (**Box 54-1**).[26] For these reasons, this chapter uses the 2022 ICC/WHO Revised 4th ed. nomenclature for PTLD and OIIA-LPDs.

Box 54-1 Current Classification Systems for Iatrogenic Immunodeficiency–Associated Lymphoproliferative Disorders (LPDs)

Three-Part Nomenclature Used by WHO Classification, Proposed 5th Ed. for Lymphoid Proliferations and Lymphomas Arising in the Setting of Immune Deficiency/Dysregulation Histologic Diagnosis: Hyperplasia (specify type), Polymorphic lymphoproliferative disorder, Mucocutaneous ulcer, Lymphoma (classify as for immunocompetent patients) Viral Association: EBV +/−, Kaposi sarcoma-associated herpesvirus/human herpesvirus 8 (KSHV/HHV8) +/− Immune Deficiency/Dysregulation Setting: Inborn error of immunity (specify type), HIV infection, Posttransplant (specify: solid organ/bone marrow), Autoimmune disease, Iatrogenic/therapy-related (specify), Immune senescence

Posttransplant Lymphoproliferative Disorders

The WHO Revised 4th ed. classification and 2022 ICC classification recognize four major categories of PTLD (**Box 54-1**).[5,8] Biopsies performed when there is a question of PTLD should be handled with a standard “rule out lymphoma” protocol that includes all the

necessary ancillary techniques required for a complete diagnosis (**Box 54-2**). Although cytologic and fine-needle aspiration biopsy specimens can be useful in some circumstances, excisional biopsy is preferred because of the importance of assessing architectural features, the need for sufficient material for ancillary studies, and the intralesional heterogeneity present in a moderate number of PTLDs.

Epidemiology

PTLDs develop in approximately 2% of all transplant recipients, with significant variation in incidence based on the type of organ transplanted: kidney, 0.5% to 3%; bone marrow or stem cell, 1% to 2%; pancreas, 1% to 2%; liver, 1% to 4%; heart and lung, 1% to 10%; and intestinal and multivisceral, 5% to 20%.[5,27-39] Some report that the incidence of PTLD has decreased over time, possibly related to increased experience, improved immunosuppressive regimens, and increased use of molecular EBV monitoring with preemptive modulation of immunosuppressive therapy; however, others have found an increasing incidence, which may be related to a rising number of transplants, older age of donors and recipients, longer survival of transplant recipients, and increasing diagnostic awareness of these LPDs.[9,28,31,40]

Box 54-2 Major Diagnostic Features of and Recommended Diagnostic Testing for Posttransplant Lymphoproliferative Disorders (PTLDs)

Morphology

- Required for diagnosis and best accomplished with histologic sections
- Findings are extremely variable: lymphoplasmacytic proliferations with underlying architectural preservation; destructive polymorphic lymphoplasmacytic proliferations with moderately numerous transformed cells or immunoblasts; and lesions fulfilling the criteria for one of the non–small cell B-cell lymphomas, an Epstein-Barr virus (EBV)-positive marginal zone lymphoma, a plasma cell neoplasm, one of the T- or natural killer (NK)-cell lymphomas, or occasionally classic Hodgkin lymphoma

Immunophenotype

- Required for diagnosis
- Findings are extremely variable, including polytypic lesions, often with many admixed B and T cells, or lesions with the classic immunophenotypic features of one of the lymphoid or plasmacytic neoplasms
- Stains for EBV should be performed, with many, but not all, cases positive using EBV-encoded RNA (EBER) in situ hybridization or, in a somewhat smaller proportion of cases, using an EBV latent membrane protein 1 (LMP1) immunohistochemical stain

Molecular/Genetics

- Variably required

- Clonal B cells are demonstrable in most cases, except in plasmacytic hyperplasia, some infectious mononucleosis (IM) PTLDs, and T- or NK-cell PTLDs
- Clonal T cells are demonstrable in T-cell monomorphic PTLD and also in some other types of PTLD
- Various additional molecular cytogenetic and karyotypic findings are related to the type of PTLD, such as *MYC* rearrangements and *TP53* mutations
- These studies are most important in recognizing T-cell PTLD and classifying some of the B-cell monomorphic PTLDs

Clinical Features

- Assessment required for patient care
- PTLDs can present with an IM-type illness, like conventional lymphoid or plasmacytic neoplasms, or sometimes with vague or absent symptoms
- PTLDs are sometimes discovered only because of routine EBV monitoring or at autopsy
- Variable outcomes, ranging from indolent with only reduction in immunosuppression to very aggressive in spite of immunochemotherapy; many different factors affect outcome

Many other factors have an effect on the incidence of PTLD. EBV seronegativity at the time of organ transplantation is an extremely important risk factor and explains in part the much higher incidence of PTLD in children than in adults.[5,31,34,38,39] Transplanting an organ from an EBV-seropositive donor into an EBV-seronegative

recipient (EBV mismatch) increases the incidence of PTLD 10-fold to 75-fold.[41] Lack of previous exposure to cytomegalovirus (CMV) is also associated with an increased incidence of PTLD if the recipient is CMV negative and either the donor is CMV positive (CMV mismatch) or the recipient experiences a symptomatic primary CMV infection.[41] The effects of EBV mismatch and CMV mismatch appear to be synergistic. Patients who undergo transplantation for hepatitis C-related cirrhosis reportedly have an increased incidence of PTLD, suggesting that hepatitis C may potentiate the oncogenicity of EBV.[42,43] Host factors, such as polymorphisms leading to lower expression of proinflammatory cytokines or greater expression of anti-inflammatory cytokines or HLA and other polymorphisms, may also influence the risk of selected PTLDs, although it has been noted that "it is currently not possible to predict which transplant patients will eventually develop PTLD."[32,44-49] Even after taking into consideration EBV and CMV serostatus, young age remains associated with an increased risk for development of PTLD, particularly early PTLD. The incidence increases again after the age of 50 years.[29,31] Overall, there is a higher incidence in males, especially for late-onset PTLD, but a higher incidence in females after small bowel transplantation.[29,40]

Another important risk factor for PTLD is the immunosuppressive regimen required to maintain or to prepare for the transplant or to treat graft-versus-host disease. The cumulative intensity of immunosuppressive therapy and the specific agents used are associated with the risk for development of early PTLD, whereas the overall duration of immunosuppression is associated with the risk for development of PTLD later.[41,50] Anti–T-cell antibody

preparations, such as OKT3 and antithymocyte globulin (ATG), have been associated with an increased risk of PTLD.[41,50-53] In adults, the frequency of early PTLD is greater in patients receiving allogeneic hematopoietic stem cell transplantation than in those receiving solid organ transplants.[52] Some of the newer immunosuppressive strategies may be associated with a lower risk for PTLD.[40,51,54,55]

Etiology

Most PTLDs after solid organ transplantation are derived from recipient lymphoid cells, whereas those occurring after hematopoietic stem cell transplantation are most often donor derived.[56,57] PTLDs limited to the allograft after solid organ transplantation are more frequently of donor origin.[58,59] The majority of PTLDs are caused by EBV-infected lymphoid or plasmacytic cells that are not adequately controlled by the immune system because of immunosuppression or, in the case of stem cell and bone marrow transplants, myeloablative regimens.[50,60,61] EBV may be acquired from the donor or other sources as a primary infection, superinfection by a second strain of EBV in a seropositive recipient, or, especially in adults, reactivation of latent recipient EBV. EBV-associated PTLD shows variable latency patterns, and individual cells can express different sets of latency proteins.[62,63] Many cases have a type III latency pattern, similar to that seen in EBV-positive lymphoblastoid cell lines; some have a type II latency pattern; and fewer have a type I pattern.[50,64,65] Classic Hodgkin lymphoma (CHL) PTLD may demonstrate a type II pattern.[63,66,67]

Patients with EBV-positive PTLD lack an effective cytotoxic T-cell response to EBV infection, with decreased EBV-specific CD8-positive

T cells and CD4-positive T cells.[68] Significantly fewer CD8-positive cytotoxic T cells have been observed in EBV-negative DLBCL-type monomorphic PTLD compared with EBV-negative DLBCL arising in immunocompetent individuals.[69,70] T-cell exhaustion, as indicated by increased expression of inhibitory receptors PD1/CD279 and LAG3/CD223, may also play a role in PTLD development.[70-73] Similarly, natural killer (NK) cells show higher levels of PD1/CD279 expression and reduced levels of cytotoxicity and activation receptors in patients with PTLD.[73] Plasmacytoid dendritic cells, which function as antigen-presenting cells in the antiviral immune response, are decreased in polymorphic and monomorphic B-cell PTLDs compared with nondestructive lesions, as well as in DLBCL-type monomorphic PTLD compared with DLBCL in immunocompetent patients.[70,74,75] PDL1/CD274, which may be induced by EBV latent membrane protein 1 (LMP1) via the JAK/STAT pathway or by gain/amplification of 9p24.1 (*JAK2/PDL1/PDL2* locus), is expressed by at least 50% of PTLD, providing additional evidence that the PD1/PDL1 pathway affords a mechanism for immune escape in these LPDs.[71,73,76] Humoral responses to EBV are diminished after transplantation, but whether this plays a role in the development of PTLD is not known.[77] Patients with PTLD reportedly demonstrate a T-helper (Th) type 2 serum cytokine profile (interferon-γ [IFN-γ]/interleukin-2 negative; interleukin-4/interleukin-10 positive) that promotes EBV-induced B-cell proliferation.[41,78]

Genetic predisposition may play a role in the development of PTLD and in patients' response to therapy. A polymorphism in IFN-γ resulting in increased synthesis is associated with early-onset and

pediatric PTLD, and a TNF gene polymorphism has been associated with the development of PTLD.[45,46,48] Polymorphic variants in the HLA system have also been associated with PTLD development, possibly because of their role in interacting with NK cells and cytotoxic T lymphocytes.[47,49,79,80]

Although very few patients demonstrate a sequential development of PTLDs, they are thought to begin as polyclonal proliferations related to EBV or other stimuli, with the development over time of oligoclonal and then monoclonal B-cell or, much less frequently, T- or NK-cell proliferations (**Fig. 54-1**).[4,81,82] Genetic and epigenetic abnormalities of the types seen in conventional lymphoid or plasmacytic neoplasms also occur as the lesions progress, making them less responsive to immune regulation.[4,6,75,83,84] Advances in the understanding of the pathways involved in the pathogenesis of PTLD are not just of academic interest as they may suggest new therapeutic strategies, such as the use of JAK/STAT or immune checkpoint inhibitors.[76,85-87]

EBV cannot be demonstrated in approximately 20% to 40% of PTLDs, with the proportion of EBV-negative cases greater now than in the past.[81,88-93] At least some EBV-negative cases may represent EBV-related proliferations that have lost the virus after transformation (hit-and-run theory).[94] Others may reflect technical difficulties in the detection of EBV, represent lymphoid proliferations driven by other viral or infectious agents, or be related to chronic antigenic stimulation, possibly by the transplant itself. Gene-expression profiling studies have suggested a difference in pathobiology, with two studies showing viral-associated changes only in the EBV-positive PTLDs, suggesting a possible nonviral etiology

for the EBV-negative cases.[95,96] Genetic studies have shown fewer copy number alterations and gene mutations in EBV-positive PTLDs compared with EBV-negative cases, and one combined genomic and transcriptomic study found that EBV-negative DLBCL-type PTLDs segregated with DLBCL arising in immunocompetent patients.[21,76,96-99] However, two additional gene-profiling studies that included a broad spectrum of PTLDs failed to distinguish EBV-positive from EBV-negative PTLDs, and one study of DLBCL-type PTLD showed a mutational profile different from DLBCL in immunocompetent patients.[83,87,99]

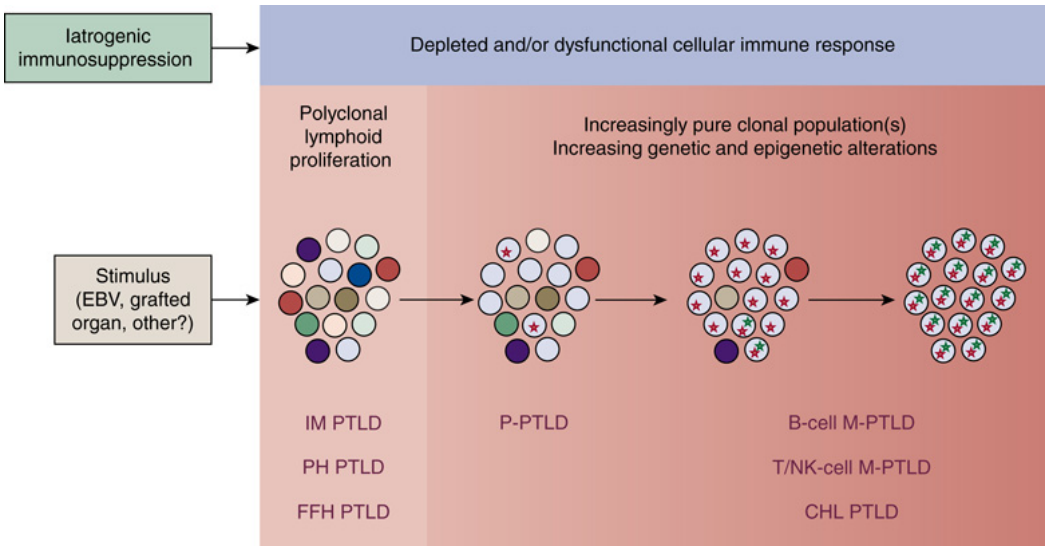

FIGURE 54-1 Model of posttransplant lymphoproliferative disorder development and correlation with clinicopathologic categories.This partially theoretical model is largely based on studies of B-cell posttransplant lymphoproliferative disorder (PTLD). Furthermore, documentation of progression through these varied stages is lacking in most cases, and the possibility that many lesions do not progress through all stages or that there may be nonlinear progression must be considered. Epstein-Barr virus (EBV) infection and, in a minority of cases, other stimuli (including chronic antigenic stimulation), in the presence of iatrogenic immunosuppression and an insufficient cellular immune response (caused by depleted or dysfunctional T cells, natural killer [NK] cells, and plasmacytoid dendritic cells), lead to a polyclonal lymphoid proliferation without

causing significant destruction of the underlying tissue structures. Cases with few transformed cells fulfill the criteria for plasmacytic hyperplasia (PH); those with a more florid proliferation, including moderate numbers of transformed cells, are infectious mononucleosis (IM) PTLD. Some nondestructive PTLD also have the morphologic appearance of florid follicular hyperplasia (FFH). Increasingly pure clonal populations develop over time that are often, but not always, of B-cell origin. These may still be PH or IM PTLD, but often fulfill the criteria for a polymorphic (P-PTLD) or B-cell monomorphic PTLD (M-PTLD). If there is a pure plasma cell proliferation, a plasmacytoma-type or multiple myeloma-type M-PTLD is diagnosed; if there are clonal T cells, one of the T-cell M-PTLDs is usually diagnosed, particularly in the absence of a B-cell PTLD or other confounding features (see text). Occasional cases are T-cell rich, sometimes resembling either a T-cell/histiocyte–rich large B-cell lymphoma or classic Hodgkin lymphoma (CHL). Cytokine production by the PTLD and other cells in the tumor microenvironment may help foster the proliferation. Additional genetic alterations may accumulate, with *BCL6* mutations caused by aberrant somatic hypermutation seen in P-PTLDs and other

abnormalities, such as *MYC* translocations, seen in some types of M-PTLD. Aberrant methylation of genes involved in B-cell activation, cell cycle regulation, apoptosis, and DNA damage repair is also common in P-PTLD and M-PTLDs. The *red stars* in the figure reflect earlier genetic/epigenetic abnormalities, such as some of the *BCL6* mutations, and the *green stars* represent later genetic/epigenetic alterations, such as *MYC* aberrations.

Rare cases of human herpesvirus 8 (HHV8)-positive PTLD have been reported, including polymorphic lesions, multicentric Castleman disease-like lesions, and primary effusion lymphoma.[100-104] Other viral associations have been less frequently reported. A metagenomic analysis of DNA viruses identified anelloviruses in 52% of PTLDs, and other viruses in a lower percentage of cases.[105] In this exploratory series, the presence of anellovirus nucleic acid sequences was associated with worse patient survival; however, further validation is required, direct causality has not been established, and some consider the presence of anelloviruses to be a marker of immunosuppression intensity.[106]

Clinical Features

Although, historically, 80% of PTLDs occur within the first year, more recent studies have suggested a median time to PTLD of several years or longer, with a wide variation between studies and with up to 15% or 25% occurring more than 10 years after transplantation.[9,27,33,107-110] Some reports describe a decrease in

the incidence of PTLD after an early phase and then a rise again at approximately 5 years, with the subsequent incidence remaining elevated.[31,33] Early-onset PTLD has been associated with younger patients; those presenting with an infectious mononucleosis (IM)–like syndrome; EBV positivity; PTLD after bone marrow, lung, heart-lung, and multivisceral transplantation; and hepatosplenic T-cell lymphoma PTLD.[9,11,32,33,52,111] Patients presenting after a longer interval reportedly are more likely to have localized extranodal disease and a worse prognosis.[16,89,112] Polymorphic PTLDs have been reported to have an earlier onset than monomorphic PTLDs; however, this could relate to the latter being more often EBV negative.[83] Monomorphic T-cell or NK-cell and CHL PTLDs are also more common among the PTLDs that occur later.[109,113] It is important to distinguish early-onset PTLD from what used to be termed "early lesions," which often occur later, with median times to occurrence of about 2 to 4 years.[114]

Patients with PTLD may have tumorous masses, often at extranodal sites; widely disseminated disease; an IM-like illness; vague, nonlocalized symptoms, such as fever; or no symptoms at all.[115] The most common sites of involvement include the gastrointestinal tract, lymph nodes, lung, and liver. Gastrointestinal tract involvement is often multifocal and may present with hemorrhage, obstruction, or perforation.[116] PTLDs may involve the central nervous system (CNS), with involvement often localized to that site.[117,118] PTLDs of the CNS are usually of monomorphic type, have a poor prognosis, and may occur relatively late after transplantation even though they are frequently EBV positive.[117,118] Nondestructive PTLDs often present with tonsil or adenoid

enlargement, although with nodal involvement in adults; and IM-like presentations are particularly common in younger patients.[114] Plasmacytoma PTLDs can be localized or disseminated, and may be associated with a paraprotein.[119,120] Approximately 20% of PTLDs occurring after solid organ transplantation are localized to the allograft.[30,121] Some PTLDs present with widely disseminated disease, including the multiple myeloma-type, which usually occurs in older patients and late after transplantation.[122-128]

EBV viral load often increases in the blood in association with PTLD, frequently before the development of overt disease, and has been proposed as a surveillance tool for high-risk patients.[17,46,129-133] Monitoring of EBV load has been suggested as one of the factors responsible for the recent decrease in incidence of some types of PTLD noted by some.[40,134] However, even EBV-positive PTLD can rarely develop in the setting of low viral loads; persistent high levels predict an increased risk of PTLD only in selected settings and may resolve spontaneously; and at least in some series, EBV loads relate more to the type of immunosuppressive regimen or the degree of iatrogenic immunosuppression.[135-140] Observation of trends in patients may be more useful than results from a single timepoint.

Morphology

The PTLDs form a morphologic spectrum from early, nondestructive polymorphic lesions to more infiltrative and destructive polymorphic or monomorphic proliferations (Boxes **54-1** and **54-2**).[5,8] PTLDs are classified largely on the basis of their morphologic appearance, but doing so can be difficult and very subjective, in part because of frequent intralesional variability or variation between different sites

of disease. Many studies report that about 60% to 80% of PTLDs are of monomorphic type, with some striking outliers at both ends of the spectrum.[9,13,33,107,109] Of the remaining cases, most studies report many more polymorphic PTLDs than nondestructive PTLD, with the latter usually making up less than 10% of cases.[13,33,107] Areas of geographic necrosis and vascular wall infiltration, and, at extranodal sites, neural infiltration are characteristic, but not required features.[2,7] Extranodal involvement may be masslike or more infiltrative, and parenchymal necrosis is sometimes present.[7] Areas adjacent to a main lesion may show more focal involvement, such as involvement of hepatic portal tracts or preservation of nodal sinuses.

Overt bone marrow involvement occurs in about 15% to 30% of patients with PTLD, and occasional patients may demonstrate peripheral blood involvement.[9,27,141-143] The bone marrow lesions, which can be either extensive or small and focal, are morphologically similar to those seen at other sites and can be found in patients with polymorphic and monomorphic types of PTLD.[141,143,144] Not uncommonly, children with PTLD may demonstrate an EBV-positive polyclonal-appearing plasmacytosis or small lymphoid or plasmacytic aggregates in the bone marrow that are of uncertain significance.[141]

Nondestructive Posttransplant Lymphoproliferative Disorders

Plasmacytic hyperplasia (PH) PTLD is usually diagnosed in biopsies of lymph nodes or sometimes tonsils in which the underlying architectural features are intact and there is a proliferation of small lymphocytes and plasma cells, with few transformed cells (**Fig. 54-**

2).[6,7] These cases are not considered PTLD by all pathologists, and particularly when EBV is lacking, they are indistinguishable from non-specific lymphoid hyperplasia.

IM PTLD is also usually diagnosed in biopsies of lymph nodes or tonsils and adenoids (**Fig. 54-3**).[4,82] The specimens demonstrate changes associated with IM in the normal host, with a florid proliferation of small lymphocytes, plasma cells, and often very prominent transformed cells and immunoblasts. Although nodal sinuses may be obscured and hyperplastic follicles may appear indistinct, the basic architecture of the lymph node or tonsil is intact. In florid cases, it may be impossible to distinguish IM PTLD from a polymorphic PTLD. As long as the changes are acceptable for IM in the normal host, the former diagnosis is preferred. IM-like changes have also been identified in other extranodal sites, such as the liver; these are often considered to be more like IM or simple EBV infection than PTLD; however, these changes may precede overt PTLD.[145] It is also important to rule out the possibility of partial nodal involvement by a monomorphic PTLD. Some nondestructive PTLDs have the morphologic appearance of florid follicular hyperplasia, without the interfollicular changes that characterize the other PTLDs of this type (**Fig. 54-4**).[5,8,114,146] Caution is advised in the absence of significant EBV positivity or a true mass lesion because otherwise the findings of florid follicular hyperplasia PTLD are totally non-specific.

As indicated, nondestructive PTLD are diagnosed in tonsils/adenoids and lymph nodes, but not generally at extranodal sites, where there may be some scattered EBV-positive cells in patients with EBV hepatitis or enteritis.[145,147,148] These may precede

or be associated with PTLD at other sites, and sometimes they are treated like a PTLD. Unless there are large numbers of EBV-positive cells, the diagnosis of a nondestructive PTLD, especially at an extranodal site, should only be rendered with extreme caution. One study of gastrointestinal biopsies in children with small bowel transplants required more than 15 EBV-encoded small RNA (EBER)-positive cells per 0.065 mm^2 "field" before a diagnosis of PTLD was rendered.[148] Also remember that infiltrates in the allograft may have a differential diagnosis of rejection, which may be present in addition to a PTLD.

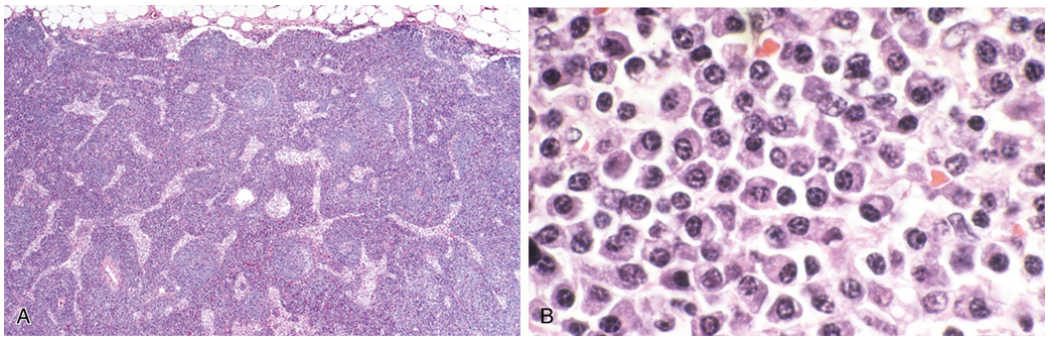

FIGURE 54-2 Plasmacytic hyperplasia in a perigastric lymph node.**A,** Normal architecture of the lymph node is preserved, with intact sinuses and occasional small follicles. **B,** Note the numerous plasma cells, which were shown to be polytypic with in situ hybridization stains for kappa and lambda. An Epstein-Barr virus–encoded RNA (EBER) in situ hybridization stain showed scattered positive cells.

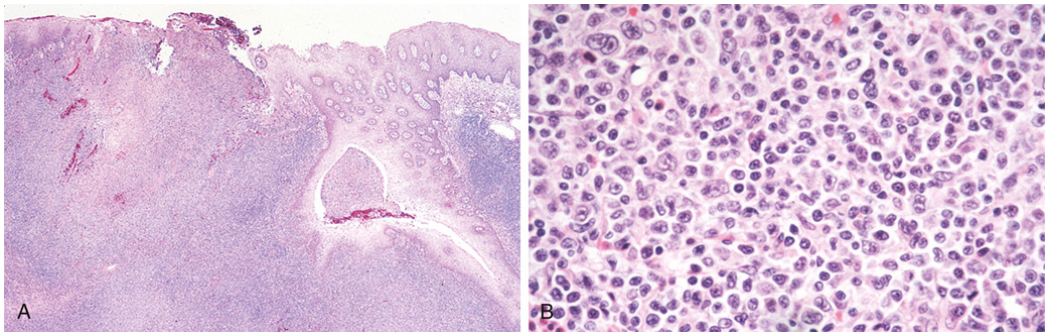

FIGURE 54-3 Infectious mononucleosis posttransplant lymphoproliferative disorder.Tonsil from an adolescent boy who presented with enlarged tonsils and adenoids and a sore throat several months after liver transplantation. The patient did well after reduction of tacrolimus immunosuppressive therapy and acyclovir treatment. **A,** Although the normal architecture of the tonsil is difficult to see, intact crypts are present. There is some superficial necrosis. **B,** The very polymorphic proliferation would be consistent with infectious mononucleosis in a normal host. Molecular clonality studies did not demonstrate evidence of B-cell clonality.

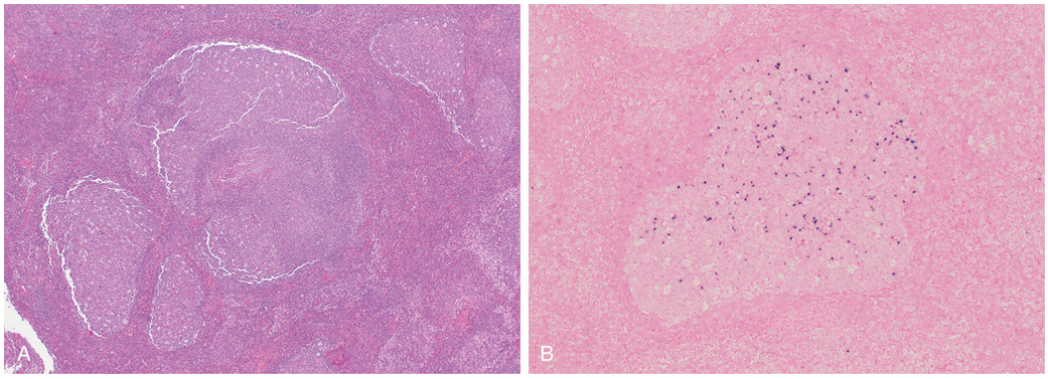

FIGURE 54-4 Florid follicular hyperplasia posttransplant lymphoproliferative disorder.Enlarged cervical lymph node from an adult man who was 8 years status post–renal transplantation. **A,** The lymph node architecture is preserved, with prominent follicular hyperplasia. **B,** An Epstein-Barr virus–encoded RNA (EBER) in situ hybridization stain shows scattered positive cells, which are particularly prominent in some germinal centers.

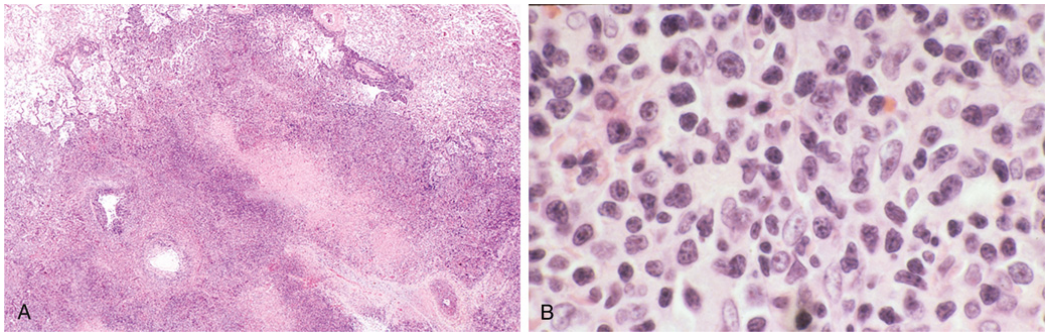

FIGURE 54-5 Polymorphic posttransplant lymphoproliferative disorder with numerous transformed cells focally.Lung from an adult man who presented with multiple pulmonary nodules 6 months after liver transplantation. **A,** Note the mass lesion, with infiltration of vascular and bronchial structures, as well as a large area of geographic necrosis. **B,** Most areas demonstrate a very polymorphic infiltrate composed of transformed cells and smaller lymphoid cells, including some with angulated nuclear contours.

Polymorphic Posttransplant Lymphoproliferative Disorder

Polymorphic PTLD, the most morphologically characteristic type of PTLD, is a diffuse and destructive proliferation of variably sized and variably shaped lymphocytes, plasma cells, transformed cells, and immunoblasts (**Fig. 54-5**).[7] Many of the small lymphocytes may have angulated or clefted-appearing nuclei and were originally thought to resemble germinal center cells. The proportion of transformed cells/immunoblasts varies, with some willing to make this diagnosis when they are very prominent (creating a

“monomorphic appearance”) and others describing them as “few.”[32,149] The immunoblasts may be multinucleated, with very prominent nucleoli resembling Reed-Sternberg cells. Many cases previously diagnosed as Hodgkin-like PTLD (a category that is no longer recognized) probably represent polymorphic PTLD and require immunohistologic studies to distinguish from CHL PTLD. Some cases demonstrate large geographic areas of necrosis that are often associated with neutrophils and histiocytes and are surrounded by increased numbers of transformed cells or immunoblasts. Apoptosis may also be present. Pulmonary cases with prominent angioinvasion and geographic necrosis resemble lymphomatoid granulomatosis. Cases that would fulfill the criteria for a lymphoma in an immunocompetent host should be categorized as one of the lymphoma-like/monomorphic PTLDs. The diagnosis of polymorphic PTLD should therefore not be used in cases that demonstrate a predominance of transformed cells or immunoblasts even if they are pleomorphic, in cases that might appear polymorphic because there are prominent transformed cells with differentiation to mature plasma cells, in cases that would fulfill the criteria for a T-cell/histiocyte-rich large B-cell lymphoma, or in polymorphic-appearing lesions that fulfill the criteria for a T-cell lymphoma.[5] The broader spectrum of what is recognized today as a lymphoma in patients without iatrogenic immunosuppression and improved immunophenotypic studies has, in essence, diminished the frequency of polymorphic PTLD, although many still use this category for polymorphic lymphoma–like PTLD. Furthermore, one gene-expression profiling study did not show segregation of polymorphic PTLD from the non–germinal center B-cell (GCB) type

of monomorphic PTLD, highlighting why this might be a difficult and somewhat arbitrary distinction to make.[83,91] At the other end of the spectrum of polymorphic PTLD are cases that overlap with florid IM PTLD where there can be some obscuring of normal architectural features, especially in some tonsillar lesions in children.[1] Some of these cases will be diagnosed as IM PTLD and others as polymorphic PTLD, largely based on pathologist preference, again highlighting the utility of being able to use PTLD as a diagnostic term rather than as only a qualifier of a specific histopathologic entity.

Some PTLDs fulfill the criteria for EBV-positive mucocutaneous ulcer (MCU).[5,150] These are variably polymorphic, well-circumscribed solitary oral or gastrointestinal tract ulcerations with prominent CD30-positive, CD20-positive, EBV-positive large B cells, often including some that resemble Reed-Sternberg cells, and with admixed T cells that often form a band at the base (**Fig. 54-6**). B-cell clonality is demonstrable in some but not all cases. Monoclonal or restricted T-cell populations are also found in the majority of MCUs,[151] although not reported in the three cases tested in the largest series of MCU PTLD.[150] These lesions have an excellent prognosis and resolve with decreased or altered immunosuppression with or without rituximab.[150] It is of interest that in contrast to most other patients with PTLD, individuals with MCU PTLD are reported to have undetectable or only very low levels of EBV DNA in their blood.[150,152]

Monomorphic Posttransplant Lymphoproliferative Disorders

Monomorphic PTLDs are lymphoid or plasmacytic proliferations that fulfill the criteria for one of the non-Hodgkin lymphomas (not of small B-cell type with the exception of EBV-positive marginal zone lymphomas) or plasma cell neoplasms that arise in immunocompetent hosts.[5] They must be further categorized on the basis of the type of neoplasm they most closely resemble.

Monomorphic B-Cell Posttransplant Lymphoproliferative Disorders

Many monomorphic PTLDs are composed of numerous transformed B cells that most commonly resemble DLBCL, NOS (**Fig. 54-7**); less commonly, Burkitt lymphoma (approximately 0%–5% of PTLDs) (**Fig. 54-8**); or more rarely, one of the other large B-cell lymphoma subtypes, such as plasmablastic lymphoma, primary DLBCL of the CNS, or primary effusion lymphoma.[9,104,107,117,118] As with other DLBCLs, the transformed B cells may be very pleomorphic, and plasmacytic differentiation may create a variable degree of pleomorphism. Some cases are T-cell rich and therefore demonstrate only a minority of large, transformed B cells. It has also been reported that large B-cell lymphoma with 11q aberrations (formerly Burkitt-like lymphoma with 11q aberrations) makes up a higher proportion of "Burkitt lymphoma" in the posttransplant setting than in immunocompetent patients.[153] This diagnosis should be suspected in *MYC* rearrangement–negative lymphomas that resemble Burkitt lymphoma, although some are less Burkitt-like and more closely resemble a DLBCL.[8]

Distinguishing polymorphic PTLD from DLBCL-type monomorphic PTLD can be extremely difficult and, to some extent,

arbitrary; there are no absolute guidelines for dealing with borderline lesions, and the clinical importance of this distinction may be limited. Some cases exhibit a definite polymorphic background but have either focal or extensive areas of numerous transformed B cells or immunoblasts. These cases are considered at least focally monomorphic in the WHO Revised 4th ed. and 2022 ICC classifications, but others have considered them polymorphic PTLD or polymorphic PTLD with numerous transformed cells.[4,5,8,149] Cases with admixed monotypic plasma cells and transformed cells or immunoblasts can also be problematic when the latter are not the dominant population; like polymorphic PTLD, such cases show a complete spectrum of B-cell maturation, but like monomorphic PTLD, these cases fulfill the criteria for a malignant lymphoma in a nonimmunocompromised host.[5]

The other major (but much less common) types of B-lineage monomorphic PTLDs include multiple myeloma and plasmacytoma-like lesions (**Fig. 54-9**). Multiple myeloma is a rare form of PTLD and should fulfill all the same criteria as in a normal host.[122-128] While most cases show a spectrum of cytologically mature to immature plasma cells, a subset may demonstrate a predominant plasmablastic cytology.[126,128] Such plasmablastic cases may have an inferior outcome.[126] Occasional cases may also have associated amyloid deposition.[126] Plasmacytoma-like lesions, which make up about 3% to 6% of PTLDs, occur most commonly in the gastrointestinal tract and skin or subcutaneous tissues, but also at nodal and other extranodal sites; they contain sheets of plasma cells that in most reports are usually “well differentiated” or mature, sometimes with occasional foci of lymphoid cells.[9,93,119,120,154,155]

Some include cases with prominent nucleoli that have not been aggressive; however, these cases will have a differential diagnosis of a plasmablastic lymphoma-type monomorphic PTLD. The cutaneous and subcutaneous cases, which are reported to account for 38% of cutaneous B-cell PTLDs, may be similar to the EBV-positive extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue (MALT lymphomas) with plasmacytic differentiation that have a predilection for the skin and subcutaneous tissues, occur late after transplantation, and usually follow an indolent clinical course.[156-158] These are currently considered a type of monomorphic PTLD.[5,8]

Among organ transplant recipients, whereas the standardized incidence ratio (SIR) for Burkitt lymphoma is 24.5 and for DLBCL is 13.5, it is not significantly increased for chronic lymphocytic leukemia/small lymphocytic lymphoma, follicular lymphoma, mantle cell lymphoma, or splenic/nodal marginal zone lymphoma.[159] The SIR is mildly increased for lymphoplasmacytic lymphoma and MALT lymphoma (both 2.8).[159] It has been specifically proposed that EBV-negative marginal zone lymphomas arising in the posttransplant setting should also be considered a form of monomorphic PTLD.[160] In one series of nine such cases, seven were of MALT lymphoma type and arose in the gastrointestinal tract.[160]

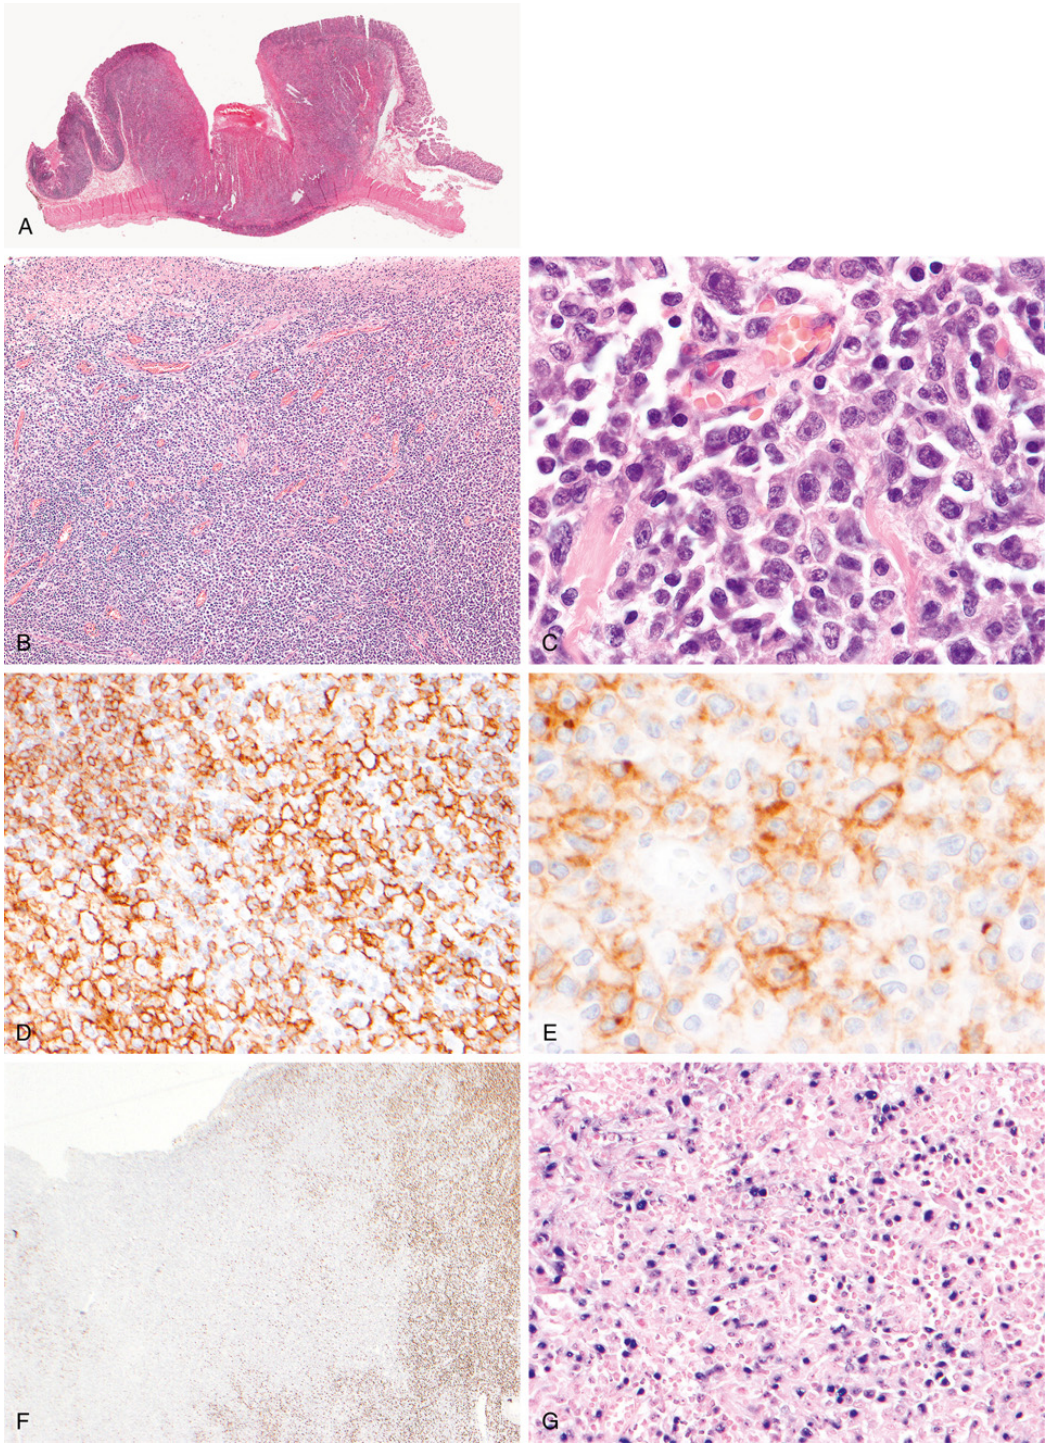

FIGURE 54-6 Posttransplant Epstein-Barr virus–positive mucocutaneous ulcer.Adult man 8 months after bilateral lung transplantation who presented with intussusception and was found to

have a single 2.0 × 1.0 × 0.5 cm ileal ulcer with no disease at any other sites. Whole-blood Epstein-Barr virus (EBV) DNA quantification by polymerase chain reaction (PCR) was negative. The patient was treated with reduction of immunosuppression and four doses of weekly rituximab, followed by four courses of maintenance rituximab, with no recurrence of disease at 60 months of follow-up. **A,** Note the dense infiltrate in the ulcerated bowel. **B,** There is a polymorphic infiltrate beneath the ulcer base that particularly, in some areas, includes **(C)** many transformed/immunoblastic cells. The infiltrate includes **(D)** many CD20-positive cells including the large cells, **(E)** a moderate number of CD30-positive cells, and **(F)** many CD3-positive T cells concentrated at the periphery of the lesion. **G,** EBV-encoded RNA (EBER) in situ hybridization stain demonstrates many EBV-positive cells. Case and images A, D, E, and G courtesy Drs. R. McKenna and L. Moench; from Hart M, Thakral B, Yohe S, et al. EBV-positive mucocutaneous ulcer in organ transplant recipients: a localized indolent posttransplant lymphoproliferative disorder. Am J Surg Pathol. 2014;38(11):1522-1529.

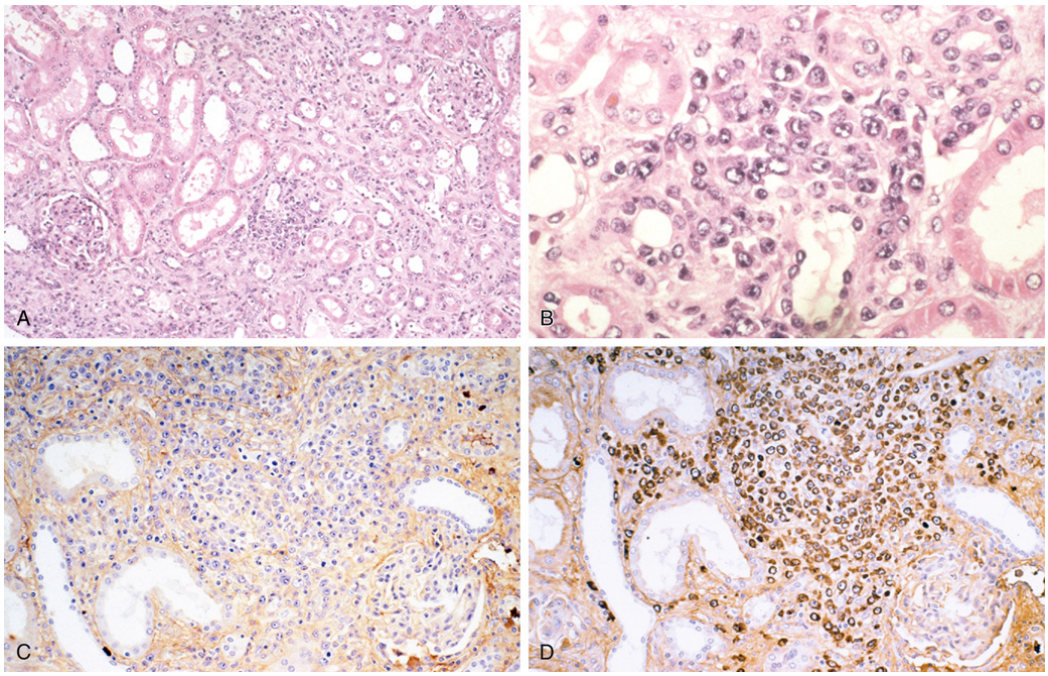

FIGURE 54-7 Diffuse large B-cell lymphoma-type monomorphic posttransplant lymphoproliferative disorder.**A,** Note the patchy infiltrate in the renal parenchyma of an adult man 4 months after renal transplantation. **B,** The infiltrate is composed predominantly of transformed and plasmacytoid-appearing large cells. In other areas, there was a prominent intravascular component. **C,** Kappa immunostain is essentially negative. **D,** Lambda immunostain is positive, supporting the monoclonality of this lesion.

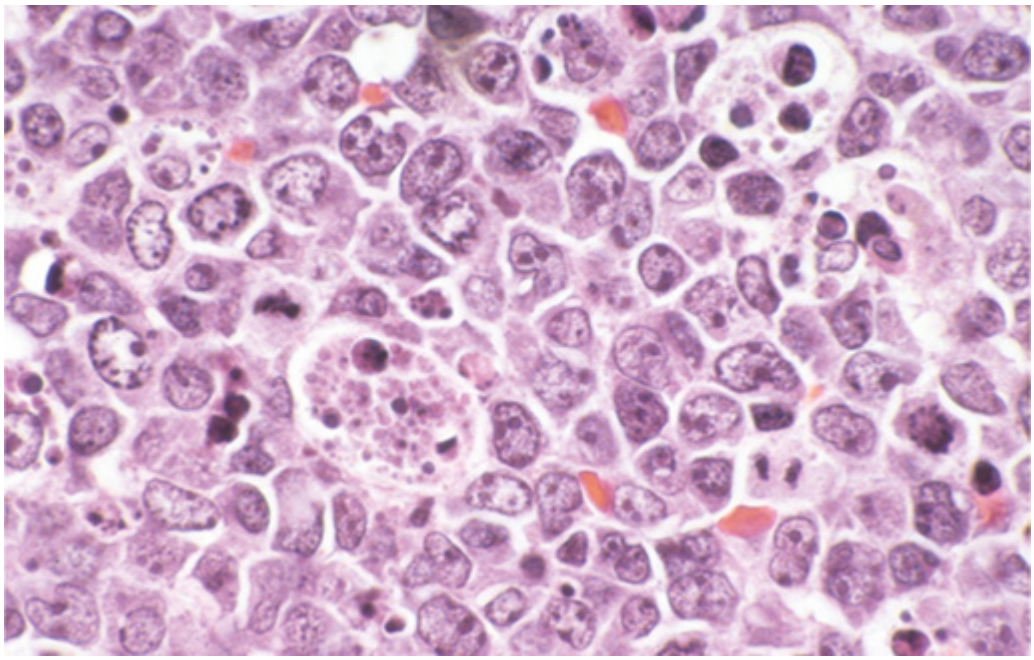

FIGURE 54-8 Monomorphic B-cell posttransplant lymphoproliferative disorder with *MYC* rearrangement.This example of posttransplant lymphoproliferative disorder (PTLD) in an adult woman after kidney transplantation is composed of intermediate-to-large-sized transformed cells. It has some Burkitt lymphoma features, with a high mitotic rate and tingible body macrophages, creating a starry-sky appearance.

Monomorphic T-Cell or NK-Cell Posttransplant Lymphoproliferative Disorders

T-cell or the rare NK-cell PTLDs account for less than 15% of PTLDs and, by definition, are monomorphic.[5,9,33,107,109,113,161,162] In contrast to most monomorphic B-cell PTLDs, the T-cell cases are not necessarily composed of predominantly large transformed cells, but

are morphologically similar to the spectrum of T-cell and NK-cell neoplasms seen in immunocompetent patients.[5,113,163] Particularly because some of these cases appear morphologically indistinguishable from polymorphic PTLDs, immunophenotypic and molecular studies are critical whenever the possibility of a T-cell PTLD is raised.[113] Most fulfill the criteria for a peripheral T-cell lymphoma (PTCL), NOS; others represent a variety of specific types of mature T-cell lymphomas (**Fig. 54-10**).[113,161-163] Approximately 15% of all hepatosplenic T-cell lymphomas occur in the posttransplant setting and make up slightly more than 10% of reported T-cell PTLDs (**Fig. 54-11**).[161,162,164] Very rare, aggressive true–NK-cell neoplasms also occur in this setting[163,165,166] and must be distinguished from indolent posttransplant T-cell large granular lymphocytic leukemia.[167,168] Posttransplant T-cell large granular lymphocytic leukemia is reported to have some clinical and laboratory features that differ from de novo cases, although there was not a significant difference in the frequency of *STAT3* mutations in one study.[169] Non-neoplastic oligoclonal increases in CD8-positive, CD57-positive T cells have been described after allogeneic hematopoietic stem cell transplantation,[170,171] and clonal CD8-positive T cells can also be seen in IM.[172] Rare cases of T-lymphoblastic leukemia/lymphoma have been reported, including some cases that could be clonally related to prior non–T-cell blastic neoplasms.[113,173] The concept that T-cell and NK-cell lymphoma-like proliferations are bona fide PTLD is supported by an overall SIR of 6.2, with a broad range depending on type, but with most having a SIR significantly greater than 1.[159] Posttransplant hepatosplenic T-cell lymphoma has a reported SIR of 100.[159]

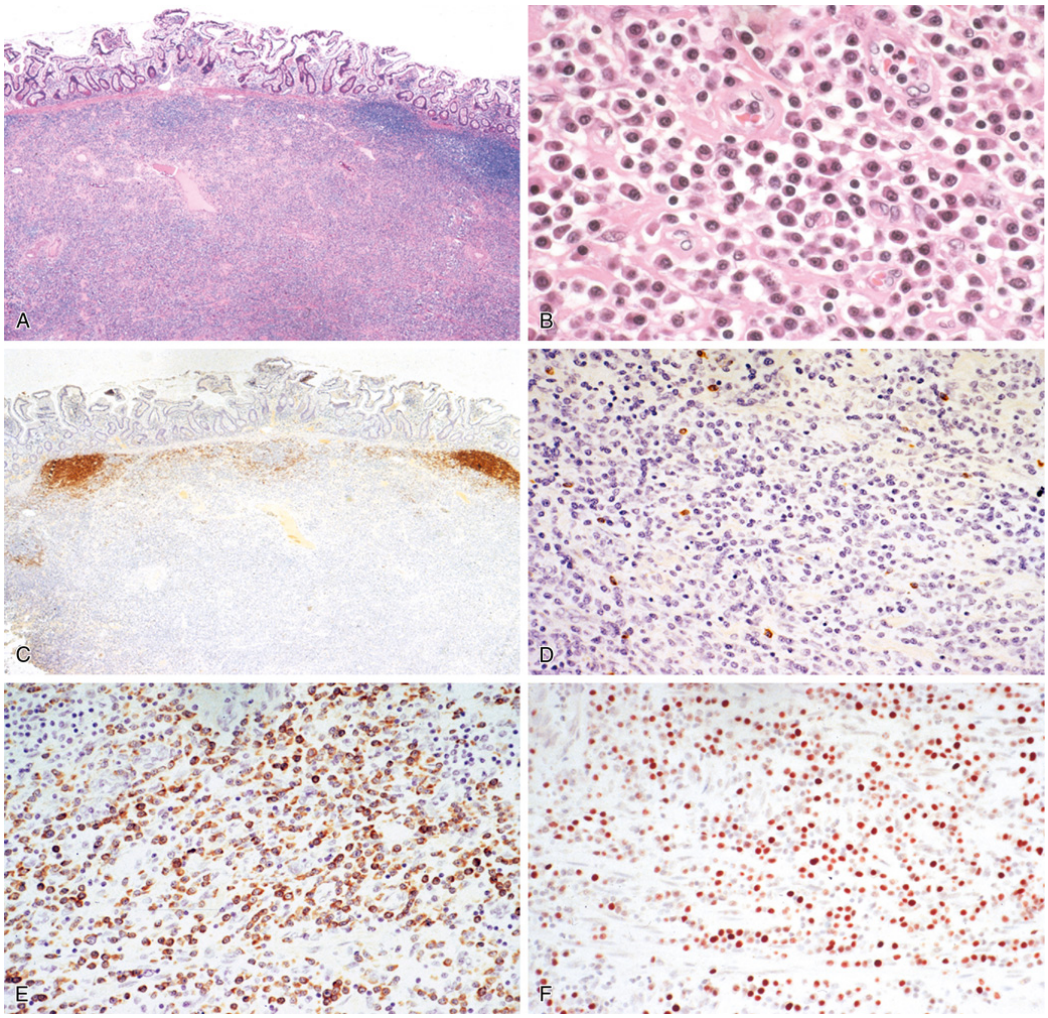

FIGURE 54-9 Plasmacytoma-type monomorphic posttransplant lymphoproliferative disorder in the small intestine.**A,** The mass lesion includes occasional lymphoid aggregates but otherwise demonstrates numerous plasma cells. **B,** There is a relatively homogeneous population of plasma cells. **C,** CD20 immunostain highlights the occasional lymphoid aggregates but is otherwise essentially negative. **D,** Kappa in situ hybridization stain is negative. **E,** Lambda in situ hybridization stain shows numerous positive

cells, supporting the monoclonality of the plasma cells. **F,** Epstein-Barr virus–encoded RNA (EBER) in situ hybridization stain shows numerous positive nuclei.

Classic Hodgkin Lymphoma Posttransplant Lymphoproliferative Disorder

CHL PTLD, the least common type, comprising 0% to 8% of PTLDs, often resembles mixed cellularity CHL.[2,9,66,107,109,174,175] These cases should fulfill both the morphologic and immunophenotypic criteria for CHL because atypical immunoblasts or Reed-Sternberg–like cells are commonly found in many PTLDs, and Hodgkin-like cases are not included in this category (Figs. **54-12** and **54-13**).[5] The CHL PTLDs are more likely to express B-cell–associated antigens (particularly OCT2, BOB1, and CD79a).[176] Some cases have occurred after non-Hodgkin lymphoma-type PTLDs.[82] They have a reported SIR of 3.6, again justifying their inclusion as a type of PTLD.[1]

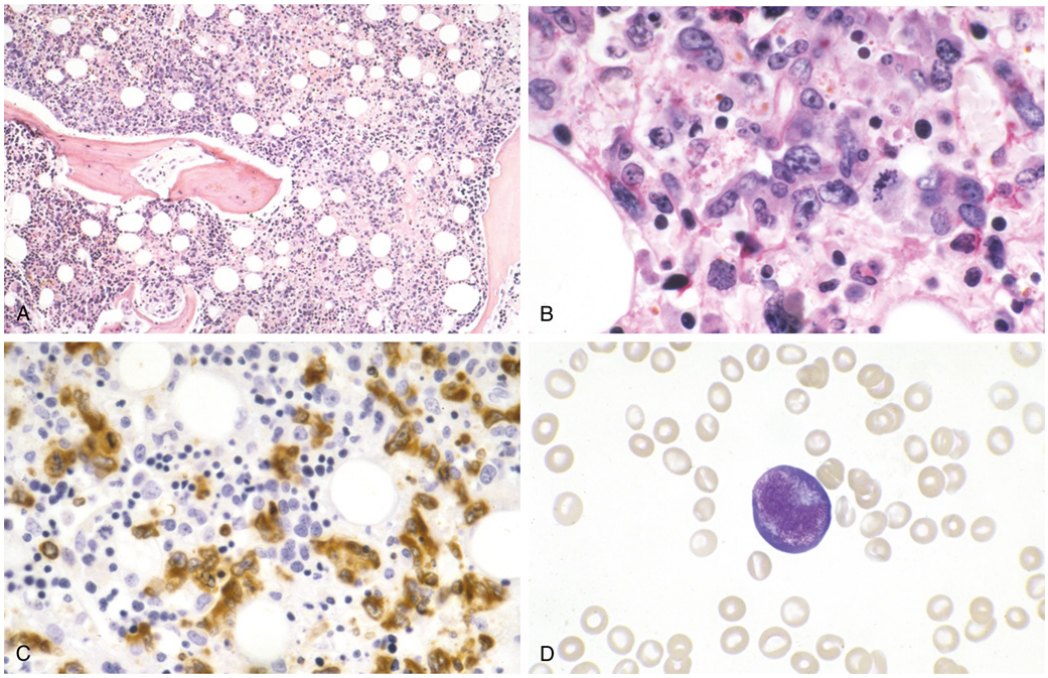

FIGURE 54-10 Peripheral T-cell lymphoma-type monomorphic posttransplant lymphoproliferative disorder.**A,** Bone marrow biopsy from a 39-year-old woman with pancytopenia, 4 years after kidney transplantation, shows a mostly interstitial large cell infiltrate admixed with hematopoietic elements, including an increased proportion of immature myeloid cells. There are also bone changes, consistent with hyperparathyroidism. **B,** The large abnormal cells have nucleoli and often irregular nuclear contours. Admixed hematopoietic elements are also seen. **C,** CD3 immunostain highlights the interstitial and scattered nature of the abnormal cells in many areas. The cells were also positive for TIA-1, indicating their cytotoxic nature, although CD4

and CD8 immunostains were both negative. The cells were negative for CD30 but positive for epithelial membrane antigen. Molecular studies demonstrated a clonal T-cell population. **D,** Peripheral blood demonstrates a small proportion of very large abnormal lymphoid cells, some of which have cytoplasmic granules.

Immunophenotype

The immunophenotype of PTLDs is variable, as would be expected for a spectrum of disorders that can resemble hyperplastic proliferations, B-cell or T-cell neoplasms, NK-cell neoplasms, CHL, or plasma cell neoplasms. In PH or IM PTLD, immunophenotypic studies do not demonstrate B-cell clonality, plasma cell clonality, or aberrant B-cell or T-cell phenotypes.[5] All types of PTLDs demonstrate variable numbers of admixed T cells, with the most numerous T cells described in IM, polymorphic, and CHL types.[177] Some cases not of clonal T-cell origin have more than 80% T cells.[178]

Polymorphic PTLDs demonstrate admixtures of B cells with variable pan–B-cell marker expression and heterogeneous T cells. Greater than 20% CD30-positive lesional cells are present in 94% of nondestructive/polymorphic PTLDs.[65] Paraffin section immunostains may demonstrate polytypic or monotypic light chain expression, and intralesional or interlesional heterogeneity with polytypic and monotypic areas or both kappa monotypic and lambda monotypic regions may be present.[7] Flow cytometric studies also show variable results.[179]

Monomorphic PTLDs have an immunophenotype consistent with that of the lymphomas in immunocompetent individuals which they resemble. Most DLBCL type monomorphic PTLDs have a non–GCB phenotype; a minority, especially EBV-negative cases, have a GCB phenotype.[83,110,180-182] CD30 positivity by more than 20% of cells is reported in 81% of DLBCL PTLDs.[65] A moderate number of T-cell PTLDs are composed of CD8-positive cytotoxic T cells that express TIA-1 and sometimes other cytotoxic granule proteins, although one meta-analysis found CD4-positive T-cell PTLDs to be slightly more

common than CD8-positive cases.[113,161,183] Some PTLDs include both B-cell and T-cell components.[184]

CHL PTLD can be diagnosed with the greatest degree of confidence when CD15-positive, CD30-positive, CD45-negative Reed-Sternberg cells are present in an appropriate T-cell–rich background; however, as in an immunocompetent host, some CD15-negative cases can be expected. The Reed-Sternberg–like cells in other types of PTLDs are expected to be CD20-positive, CD45-positive, and CD15-negative. A CD30-negative immunophenotype makes CHL PTLD extremely unlikely, but CD30 positivity cannot help in the distinction between CHL PTLD and other types of PTLD.[5]

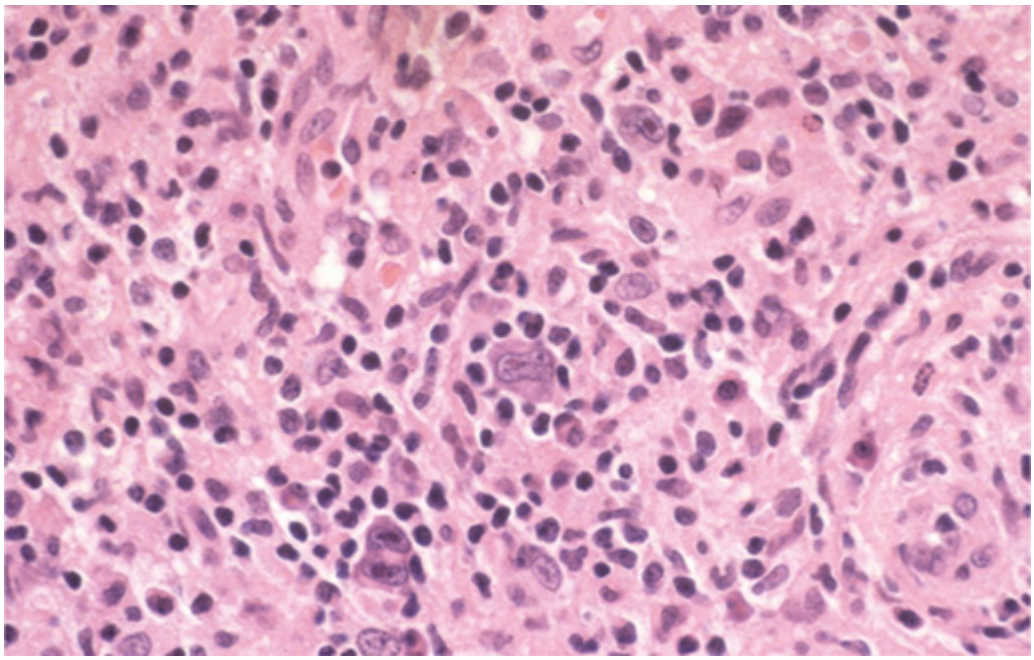

FIGURE 54-12 Mixed cellularity classic Hodgkin lymphoma posttransplant lymphoproliferative disorder (PTLD) in an adult man after kidney transplantation. Note the Reed-Sternberg and Reed-Sternberg variant cells admixed with numerous small lymphocytes, plasma cells, and histiocytes.

About 60% to 80% of PTLDs are associated with EBV, as best demonstrated by EBER in situ hybridization, although some find a much higher proportion of EBV-negative cases.[9,32,81,88-90,92,93,107,185] EBER in situ hybridization is more sensitive than the immunohistochemical stain for EBV LMP1, but it is also somewhat more likely to be positive in the absence of a diagnosable PTLD and is dependent on preservation of RNA.[5,186] Most PTLDs have a latency type III EBV pattern and thus are positive for both LMP1 and

EBNA2, a combination that suggests immunodeficiency. EBV-negative PTLDs are more often monomorphic compared with EBV-positive cases.[88,89] EBV is described in all other types of PTLDs, although multiple myeloma cases are often negative and CHL cases are almost always positive. Some also find nondestructive PTLD to be uniformly EBV positive.[114] Cases of EBV-negative PH or florid follicular hyperplasia are completely indistinguishable from a non-specific hyperplasia. About one-third of T-cell PTLDs are EBV positive, as are at least some of the rare NK-cell neoplasms.[113,161,162,166]

Genetics

Clonality Studies

Almost all polymorphic PTLDs and monomorphic B-cell PTLDs are monoclonal on the basis of immunoglobulin gene-rearrangement studies or EBV terminal repeat analysis.[6,102,187] With the very sensitive latter technique, even many IM PTLDs are demonstrably clonal, as are some cases of PH and even occasional hyperplastic lymph nodes in a nontransplantation setting.[188] Genotypic studies demonstrate occasional cases with more than one clone or with an oligoclonal B-cell proliferation. Monomorphic PTLDs usually have more dominant clones than polymorphic PTLDs.[189-191]

Distinct simultaneous or subsequent lesions in the same patient may show different B-cell clones or a monoclonal population at one site and a polyclonal population elsewhere.[6,7,189] The presence of numerous clonally distinct PTLDs is particularly well recognized in the gastrointestinal tract.[192] A recent study suggested that when multiple synchronous or metachronous PTLD are EBV positive, they

are often clonally unrelated, but recurrent or multiple EBV-negative lesions appear to more often represent clonally related lesions.[193] Studies of IGHV gene usage and mutational patterns suggest that antigen selection may be important in the development or progression of PTLDs.[82,83,194] A minority of cases show crippling IGH mutations.[83] T-cell clonality is documented in the majority of monomorphic T-cell PTLDs. Occasional cases can be shown to have both clonal B cells and T cells either simultaneously or in different lesions.[184] Caution is advised, as one study reported half of B-cell PTLDs have monoclonal T-cell populations, usually in the absence of a recognizable T-cell PTLD, and especially in the presence of a predominance of CD8-positive T cells.[195]

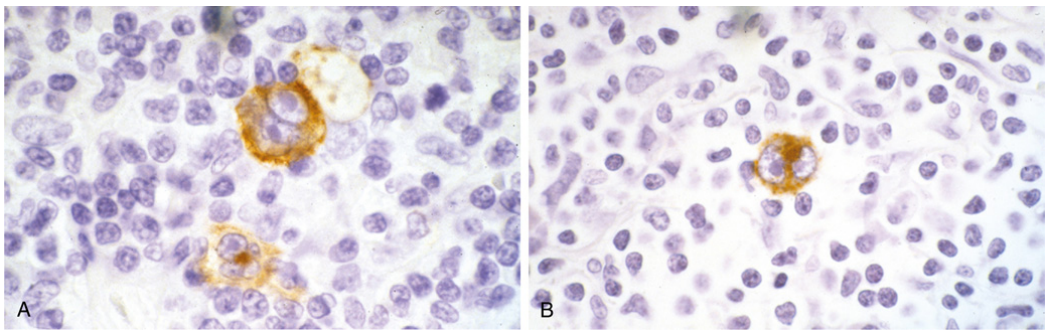

FIGURE 54-13 Classic Hodgkin lymphoma posttransplant lymphoproliferative disorder. **A,** CD30 stain highlights a Reed-Sternberg cell. **B,** Reed-Sternberg cells are also highlighted by an Epstein-Barr virus (EBV) latent membrane protein 1 immunostain.

Genetic and Epigenetic Studies

Classical cytogenetic studies document clonal abnormalities in a variable proportion of PTLDs; however, the limited published studies have not shown consistent recurrent abnormalities.[2,76,144,146,196] Abnormalities are most commonly found in monomorphic PTLDs, but are also reported in some polymorphic PTLDs and even occasional nondestructive PTLDs.[87,97,146,196] Some of the more commonly reported abnormalities in B-cell PTLDs include trisomy 9, trisomy 11, 8q24/*MYC* rearrangements (enriched in Burkitt lymphoma and plasmablastic lymphoma-type monomorphic PTLDs), 14q32 rearrangements, and breaks at 1q11-21.[146,153,197-199] Monomorphic PTLDs that often resemble Burkitt lymphoma but lack *MYC* rearrangements and demonstrate a chromosome 11q23 gain/11q24 loss pattern similar to that seen in immunocompetent patients have been reported.[153] *BCL2* and *BCL6,* but not *CCND1,* gene rearrangements are described in rare PTLDs, as well as a small number of cases with *MYC, BCL2,* or *BCL6* gains.[6,64,184,200,201] Comparative genomic hybridization/single nucleotide polymorphism analyses have demonstrated a variety of recurrent chromosomal gains and losses, as well as some high-level amplifications, with some similarities and differences from DLBCL in immunocompetent hosts; however, the precise findings are inconsistent.[20,21,97,98] A subset of DLBCL-type monomorphic PTLD and CHL PTLD have gains/amplification of chromosome 9p24.1, the *JAK2/PDL1/PDL2* locus, which may have implications for potential checkpoint inhibitor therapy.[76,176] Karyotypic and fluorescence in situ hybridization analyses of multiple myeloma-type PTLDs demonstrate a spectrum of cytogenetic abnormalities typical for myelomas in immunocompetent individuals.[126-128]

BCL6 mutations are reported to be absent in PH and to be present in 43% of polymorphic PTLDs and 90% of monomorphic B-cell PTLDs.[84] Others, however, have found similar proportions of *BCL6* mutations in polymorphic and monomorphic PTLDs.[83] Aberrant somatic hypermutation involving genes other than *BCL6* is also reported to be more common in monomorphic than in polymorphic PTLDs, but is reported to be less frequent than in DLBCL arising in immunocompetent hosts.[83,96] A more recent high-throughput sequencing study showed fewer mutations in polymorphic and EBV-positive DLBCL-type monomorphic PTLD compared with both EBV-negative DLBCL PTLD and DLBCL occurring in normal hosts.[99] A low number of mutations and copy number alterations were also reported in a small series of EBV-positive MALT-type monomorphic PTLDs.[158] Mutations of *TP53* and *KMT2D* were reported in 36% of DLBCL-type monomorphic PTLDs in one study, as well as recurrent mutations of *BTG1, MYC, MYD88, PIM1,* and *TET2* in more than 10% of cases.[99] Although a second study confirmed the relatively high prevalence of *TP53* mutations in DLBCL-type PTLD, a more recent study did not and instead noted recurrent *JAK3* mutations in both monomorphic and CHL PTLDs.[87,198] Alterations of *TP53* and *KMT2* family genes are also frequent in plasmablastic lymphoma-type monomorphic PTLDs.[199] Mutations of MAP kinase pathway genes, including *NRAS,* have been described in monomorphic B-cell PTLDs, including multiple myeloma and plasmablastic lymphoma types.[6,199] *IFNA* gene deletion has been reported in 44% of monomorphic PTLDs, but in 1.7% of other intermediate- to high-grade non-Hodgkin lymphomas.[202] Acquisition of mutations has

also been associated with disease recurrence and progression in a limited number of patients with B-cell PTLD studied.[83]

Monomorphic T-cell and NK-cell PTLDs show similar genetic alterations as T-cell and NK-cell lymphomas arising in immunocompetent individuals.[163] *TP53* and other oncogene mutations or deletions are reported in a high proportion of T-cell and NK-cell PTLDs, and JAK/STAT pathway genes are also commonly mutated.[163,203] Monomorphic T-cell and NK-cell PTLDs frequently exhibit complex copy number alterations.[163] Characteristic isochromosome 7q and trisomy 8 are found in hepatosplenic T-cell lymphoma-type monomorphic PTLD.[164]

In addition to genetic alterations, aberrant methylation as an epigenetic mechanism to silence tumor suppressor genes and initiate B-cell activation is implicated in the development of PTLDs.[32,75,204] Hypermethylation of genes involved in apoptosis, cell cycle regulation, and DNA damage repair is common in polymorphic and monomorphic PTLDs.[75] *DAPK,* which encodes a serine-threonine kinase that plays a role in apoptosis initiated by TNF-α, IFN-γ, and FAS, is hypermethylated in 76% of monomorphic PTLD.[75,205] Similarly, both polymorphic and monomorphic PTLD frequently show increased methylation of the DNA repair gene *MGMT*.[75,205] Approximately three-quarters of polymorphic and DLBCL-type PTLDs exhibit hypermethylation of *PTPN6,* which, under normal circumstances, functions as an inhibitor of the JAK/STAT pathway.[75] EBV modulates DNA methylation via LMP1 and EBNA proteins, and very likely contributes to the altered methylation pattern in at least a subset of PTLDs.[32,204]

Postulated Normal Counterparts

The postulated normal counterparts are mature follicular or postfollicular B cells, plasma cells, and postthymic T cells.

Clinical Course

PTLD is a serious complication of transplantation and can be associated with significant morbidity and mortality. Reported mortality rates vary widely, with many reports published before the current era of widespread rituximab use.[32] Recent cohorts report 3-year overall survivals ranging from 49% to 73%, with multiple factors influencing outcomes, including patient age, type of transplant, distribution of PTLD subtypes, and proportion of patients receiving rituximab.[9,13,33,107] With appropriate therapy, patients with lymphoma-type PTLD are reported to have survivals like those of patients in the general population with similar lymphomas.[11] However, a uniform PTLD treatment strategy does not exist, and it is an area with many controversies, in part because of the protean nature of these LPDs.[9,16,17,116,206-209] On one end of the spectrum, patients with nondestructive PTLDs often do very well with only surgery or with the addition of decreased immunosuppression; on the other end of the spectrum, monomorphic PTLDs, especially some types, often require some component of chemotherapy.[16,23,114,210] Most patients are treated, at least in part, with a decrease in their immunosuppressive regimens whenever possible, keeping in mind that the patient's well-being is dependent on the status of the allograft.[16]

Although decreased immunosuppressive therapy often remains the first line of treatment for PTLD, addition of other therapeutic modalities is a frequent practice either up-front or

sequentially.[16,17,210] Surgical excision and sometimes radiation therapy for localized lesions are other important and frequently successful therapeutic strategies in appropriate cases.[18,210] Rituximab, used as monotherapy or in combination with chemotherapy, is an important component of treatment for polymorphic and monomorphic B-cell PTLDs. A commonly accepted treatment strategy for polymorphic and DLBCL-type monomorphic PTLDs arising in adults after solid organ transplantation is a sequential approach beginning with reduction of immunosuppression, if possible, with or without treatment with rituximab and followed by R-CHOP (rituximab, cyclophosphamide, doxorubicin hydrochloride, vincristine sulfate, and prednisone), if necessary.[10,210-212] The success of rituximab monotherapy in a significant number of patients with monomorphic B-cell PTLD highlights an important clinical difference from DLBCL, NOS in immunocompetent hosts, where rituximab alone would not be considered acceptable therapy. Although a sequential approach may be appropriate for many monomorphic B-cell PTLDs, upfront R-CHOP can be beneficial in selected high-risk patients in whom rapid attainment of response is desirable.[212] In the pediatric solid organ transplant setting, treatment of polymorphic and monomorphic B-cell PTLDs relies on low-dose chemotherapy (cyclophosphamide and either prednisone or methylprednisolone) combined with rituximab.[16,191,213] Preemptive rituximab therapy, based on EBV viremia and lack of T-cell reconstitution, may prevent the development of PTLD in the setting of allogeneic hematopoietic stem cell transplantation.[214] Less common subtypes of monomorphic PTLD, such as Burkitt lymphoma, primary CNS lymphoma, T-cell

and NK-cell lymphomas, multiple myeloma, and CHL PTLD, are usually treated in a similar manner to these neoplasms arising in immunocompetent patients.[16,17,134,138,210,215,216] A trial of reduced immunosuppression is often omitted in the treatment of these rare PTLD subtypes.

Aside from reduced immunosuppression, rituximab, and chemotherapy, a variety of novel treatment strategies for PTLD, including other monoclonal antibodies and small molecule or checkpoint inhibitors, are under investigation.[16,18,213,217] Antiviral agents have been widely used, but with the possible exception of some newer strategies, they have not been very effective in PTLD.[206] Another strategy is the use of adoptive T-cell therapy with donor-derived unfractionated or EBV-specific cytotoxic T cells.[16,18,213,218-225] A variety of active clinical trials are also underway evaluating chimeric antigen receptor T-cell therapy.[16,18,213]

Prognostic factors are another problematic area; the literature is inconsistent, and one must consider the specific type of PTLD and the clinical setting. The protean nature of PTLD and data primarily from single center analyses makes validation of prognostic factors challenging.[210] Nevertheless, several prognostic factors that are probably applicable in many PTLDs have been reported, although rigorous proof does not exist for many, and it is not always known which are independent prognostic indicators. One important predictor of outcome is response to a trial of decreased immunosuppression; however, the proportion of responding patients is variable, and those who fail to respond may still be cured of their disease.[116,206,208] Response to therapy in general is associated with a superior prognosis.[9] PTLD after allogeneic hematopoietic stem cell

transplantation has a very poor prognosis, with reported survival rates of 8% to 20% and with long-term survival described as suboptimal.[57,226-228] Many solid organ transplant patients fare better, and those with PTLD of donor origin reportedly have better outcomes than those with the much more common PTLD of recipient origin.[58,59] PTLD localized to the allograft is usually associated with a good prognosis, with about three-quarters of patients surviving.[59,116,229] Although many patients who present with an IM syndrome have a good outcome, some go on to develop rapidly progressive PTLD that may be fatal.[230-232] CNS, bone marrow, and serous effusion involvement are all adverse prognostic indicators, as is hypoalbuminemia.[9,27,233-235] PTLD presenting as disseminated disease has been associated with a survival rate of less than 10%.[229] Elevated lactate dehydrogenase, organ dysfunction, CNS involvement, and multiorgan involvement adversely affect the likelihood of responding to decreased immunosuppression.[206,233] There is conflicting data regarding the value of the International Prognostic Index (IPI) in the setting of PTLD.[9,11,27,65,211,212,236-243] In pediatric patients, CD20 expression, age ≤16 years, and good performance status are associated with better survival, while a poor response to initial treatment and allograft rejection are associated with inferior survival.[243-245] The latter highlights how treatment of patients with PTLD must also take into consideration the implications for the transplanted organs, with loss of the allograft another cause of morbidity and, depending on the type of transplant, mortality.

Data concerning the prognostic implications of pathologic subtype are limited; however, some generalizations can be made. Patients

with one of the nondestructive PTLD generally do well, whereas those with monomorphic PTLD appear to be less likely to respond to decreased immunosuppression and have a worse prognosis.[114,231,246,247] The degree to which patients with polymorphic PTLD do better than those with monomorphic PTLD, if at all, is controversial; some investigators report major differences, and others report no differences, sometimes with excellent survival even among those with monomorphic disease.[9,27,41,65,142,191,246,248-252] With modern therapies, the overall survival of post–solid organ transplant multiple myeloma is comparable to that in immunocompetent individuals.[6,122,126] Plasmacytoma PTLD appears to have a more variable outcome, but more recent publications emphasize how many of them do well, even oftentimes with limited treatment and sometimes with just a reduction in immunosuppression.[9,93,119,154,253] Nonetheless, some cases require more aggressive, often myeloma-type therapy.[120,154,254] Except for cases of indolent T-cell large granular lymphocytic leukemia, PTLDs of T-cell or NK-cell phenotype are often, but not invariably, associated with a poor prognosis, with the hepatosplenic T-cell lymphoma type doing extremely poorly.[113,161] Although data is limited, pediatric solid organ transplant recipients with CHL PTLD are reported to have good outcomes when treated with standard CHL regimens, with an overall survival ranging from 86% to 100% at 5 years.[255,256] A recent meta-analysis of adult solid organ transplant recipients with CHL PTLD suggested improved outcomes in this group since 2000, and a single institution study of patients with PTLD diagnosed between 1987 and 2017 reported CHL PTLD to have the best prognosis of all the PTLD, with a reported

median survival of 197.1 months and a 100% 2-year overall survival.[107,257]

Although PTLDs with B-cell "clonality" demonstrated principally by immunophenotyping are more frequently resistant to decreased immunosuppression than are polyclonal-appearing PTLDs, a significant number of the former patients respond to this therapeutic strategy.[7,142] Secondary *NRAS* and *TP53* mutations and *MYC* translocations have also been associated with a poor prognosis.[6,189,196,197] Absence of detectable EBV is associated with a worse prognosis in some studies but not in others.[27,88,91,107,211,212]

Differential Diagnosis

The possibility of specific infectious or other inflammatory processes must always be ruled out when lymphoplasmacytic infiltrates are seen in posttransplant patients. These diagnoses may be based on the presence of viral inclusions or other organisms, the assessment of pathologic findings that suggest another specific diagnosis, and even the clinical situation, to some extent. Extensive EBV positivity or findings associated with any of the B-cell or T-cell lymphomas support the diagnosis of PTLD. Transplant patients may also have lymph node biopsies that show a completely non-specific hyperplasia, with architectural preservation and an absence of EBV. It is important to question whether such lymph nodes are representative of whatever is causing the clinical concern. Lymphadenopathy may also occur as an apparent allergic reaction to the therapeutic use of OKT3 and ATG.[258]

When allograft biopsies are being evaluated, the distinction from florid rejection can be difficult. The presence of expansile nodules or

a mass lesion, numerous transformed cells, lymphoid atypia, a very B-cell–rich infiltrate, extensive serpiginous necrosis within the infiltrate, a high proportion of frank plasma cells, and evidence of many EBV-positive cells are among the features that support the diagnosis of PTLD rather than rejection.[90,259-261] Necrosis by itself and venous wall infiltration are not helpful findings. Significant arterial infiltration and variable numbers of eosinophils are among the features favoring rejection. Caution is advised, however, because PTLD can infiltrate arterial walls, have numerous T cells, and lack atypia. Conversely, some inflammatory processes, including in transplant patients, may have scattered (≤10%) EBV-positive cells.[148,260,262] Lesions not diagnostic of PTLD but with scattered EBV-positive cells may be associated with PTLD at another site or with an increased risk for development of PTLD.[145,148] Some allografts demonstrate evidence of both PTLD and rejection.

Iatrogenic Immunodeficiency-Associated Lymphoproliferative Disorders in Nontransplant Settings

Outside the transplantation setting, OIIA-LPDs have been described in patients receiving a number of immunosuppressive/immunomodulatory agents or cytotoxic therapies.[5,263-271] Some of the implicated agents are the same as or similar to those used after transplantation, such as antimetabolites (azathioprine, 6-mercaptopurine, mycophenolate mofetil), calcineurin inhibitors (cyclosporine, tacrolimus), and corticosteroids.[264,270,272,273] Others include immunosuppressive/immunomodulatory agents used in therapy for

autoimmune disorders or lymphoid neoplasms, such as methotrexate, TNF-α inhibitors, integrin antagonists, and fludarabine.[263,267,268,274-276] Rare cases associated with JAK or tyrosine kinase inhibitors are also described.[277-280] Assessment of whether a specific agent is responsible for an LPD is complicated by the fact that the patient's underlying disorder may be associated with an increased incidence of lymphoma, or oftentimes the patient is receiving more than one immunosuppressive/immunomodulatory agent.[265]

The best recognized OIIA-LPDs are those associated with methotrexate in patients being treated for rheumatoid arthritis, dermatomyositis, and, rarely, psoriasis.[5,14,265,268,281,282] These patients usually have long-standing rheumatic disease (often as long as 15 years), are receiving methotrexate at the time of diagnosis, and have been taking methotrexate for a median of 3 years.[14,268,283,284] About half the cases involve one or more extranodal sites.[14,281,284] Methotrexate-associated LPDs form a morphologic spectrum similar to that of the PTLDs, but with a different distribution among the morphologic subtypes.[5,269,281,283-285] Most commonly, cases fulfill the criteria for DLBCL (**Fig. 54-14**). Only a relatively small proportion of cases resemble polymorphic PTLD or are described as a lymphoplasmacytic infiltrate (**Fig. 54-15**).[269,285,286] Although an infrequent type of PTLD, approximately 25% of cases reportedly fulfill the criteria for CHL of mixed cellularity or another type.[270,285,286] Caution is advised because many "Hodgkin-like" lesions are also described in this setting. A small proportion of the monomorphic cases represent PTCLs, most commonly angioimmunoblastic T-cell lymphoma, with rare cases described as

T-cell large granular lymphocytic leukemia.[287,288] Finally, some cases included in series of methotrexate-associated LPDs are small B-cell neoplasms of varied types.[283-286] Although series vary, about 40% of the methotrexate-associated LPDs are EBV positive, including some follicular lymphomas and marginal zone lymphomas; the CHL type have the highest proportion of EBV-positive cases.[5,157,265,269,270,281,284,285,287] EBV-positive nondestructive, reactive lymphoid hyperplasias are also reported in association with methotrexate, with most cases characterized by a follicular hyperplasia.[269,286]

Very little data exist about the genetic basis of methotrexate-associated LPDs; however, most appear to have a clonal immunoglobulin gene rearrangement, including polymorphic cases.[283,285,289] One study that performed copy number analysis of methotrexate-associated DLBCL showed a higher frequency of chromosome 3q, 12q, and 20p gains compared with DLBCL in immunocompetent patients.[289] Loss of *TNFRSF14* and *TNFAIP3* gene loci was found in 40% and 25% of cases, respectively. EBV-positive methotrexate-associated DLBCLs also appeared to harbor fewer copy number alterations than EBV-negative cases.[289] A recent mutational analysis of methotrexate-associated DLBCLs showed frequent mutations of *KMT2D, TNFRSF14,* and *MYC*.[285] *TP53* mutations have been documented in 10% to 15% of cases.[285,290]

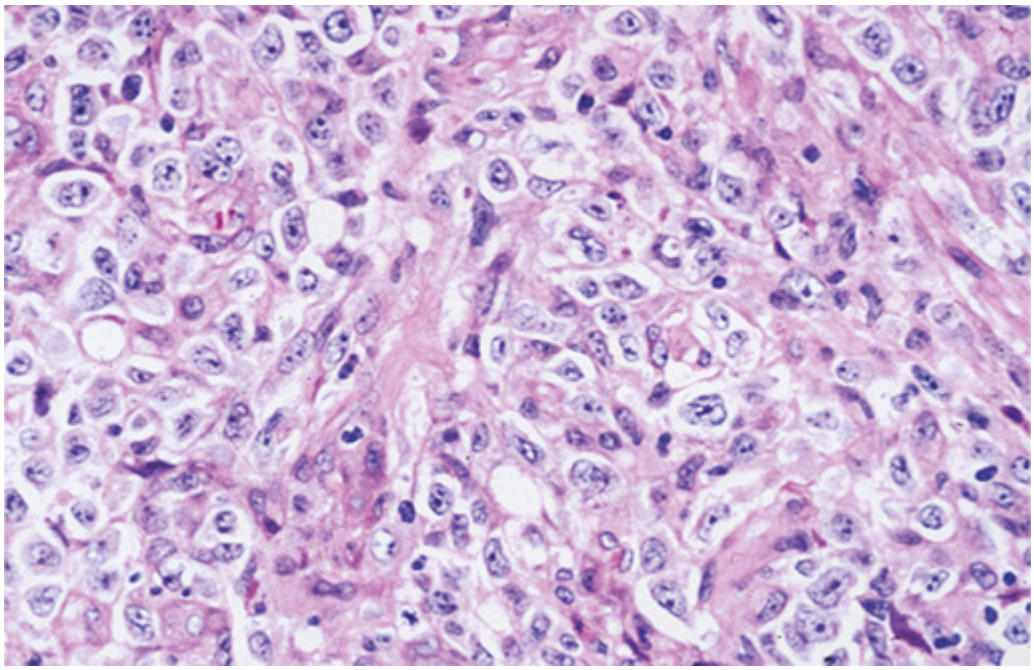

FIGURE 54-14 Diffuse large B-cell lymphoma methotrexate-associated lymphoproliferative disorder (Epstein-Barr virus [EBV]-positive) in a patient with rheumatoid arthritis.This relatively monomorphic proliferation of large, transformed B cells is indistinguishable from many diffuse large B-cell lymphomas in normal hosts. Courtesy Dr. Nancy Lee Harris.

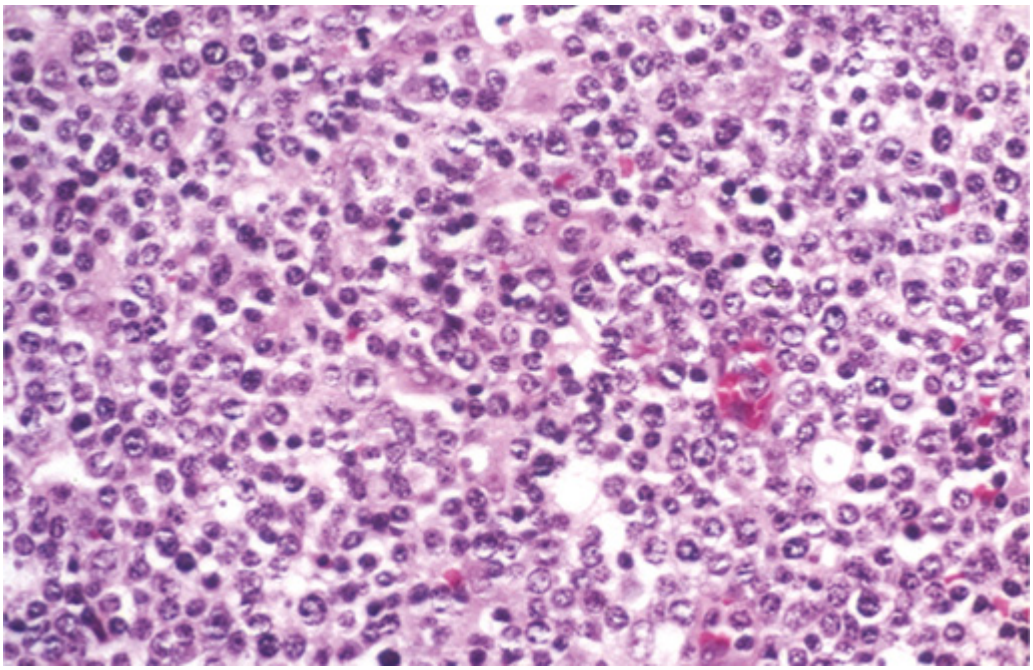

FIGURE 54-15 Polymorphic methotrexate-associated lymphoproliferative disorder (Epstein-Barr virus [EBV]-positive) that regressed after cessation of methotrexate therapy.There is a diffuse proliferation of very heterogeneous lymphoid cells. Courtesy Dr. Nancy Lee Harris.

Recognition of methotrexate-associated LPD is important because approximately 60% of patients respond to withdrawal of methotrexate therapy.[5,269,283-285] EBV-positive methotrexate-associated LPDs are most likely to respond; however, some responses are seen with EBV-negative lesions.[281,283-285,291] CHL-type cases have also responded in some but not all reports.[284,285] Of the cases that show regression, approximately 20% will eventually recur and require conventional lymphoma therapies, although this percentage does vary between studies.[269,283,285] A small study using a simplified genetic algorithm that correlated with the LymphGen

classifier reported that patients with methotrexate-associated DLBCL who had a clinical response to methotrexate withdrawal alone had fewer variants than patients who required additional chemotherapy.[292] Although 83% of the LPDs in patients who did not require chemotherapy were unclassified by their genetic algorithm, 75% of LPDs from those who required chemotherapy could be categorized, with most cases falling within the MYD88 group (37.5%), and the remainder in the BCL2 (25%) and SGK1 (12.5%) groups.[292]

A subset of the methotrexate-associated LPDs have the features of EBV-positive MCU, which is considered a distinct entity in the WHO Revised 4th ed. and 2022 ICC classifications.[5,8,151,293] Other methotrexate-associated cutaneous LPDs, which may share some features with EBV-positive MCU, are also described. Not all of these are EBV positive, and they can look very worrisome, but often the patients do well with discontinuation of the methotrexate with or without other local therapies.[291,294]

Infliximab and other TNF-α antagonists have been associated with LPDs of varied types in patients with autoimmune diseases, with B-cell lymphoma–type lesions the most common and polymorphic lesions rare.[263,295] EBV has been associated with the B-cell and CHL-type lesions.[263] At least some of the nonlymphomatous lesions may respond to withdrawal of the immunomodulatory therapy.[263] Infliximab, in combination with azathioprine or mercaptopurine, has been specifically associated with hepatosplenic T-cell lymphomas in young patients with Crohn's disease; only rare cases have been associated with TNF-α inhibitor monotherapy.[5,266,267,296,297] The hepatosplenic T-cell lymphomas in these patients do not differ from

those in immunocompetent hosts, do not respond to decreased immunosuppressive therapy, and are almost uniformly fatal. There are also a very small number of older and female patients who have developed hepatosplenic T-cell lymphoma in the setting of TNF-α inhibitors for inflammatory bowel disease or rheumatoid arthritis.[296] An increased risk for mycosis fungoides/Sézary syndrome is also reported in association with TNF-α inhibitor exposure.[296,298] Although many uncertainties still exist in terms of lymphoma risk,[296,299] it is well established that TNF-α inhibitors have a profound effect on the immune system and infliximab has been associated with EBV reactivation and an increased EBV viral load that reverses after discontinuation of the drug.[300-302] LPDs have also been reported in patients receiving other biological agents, such as rare CNS lymphomas associated with the integrin antagonist natalizumab used in the treatment of multiple sclerosis.[274]

Small molecule inhibitors used in the setting of autoimmune diseases and myeloid neoplasms have been associated with a variety of LPDs. Rare polymorphic or monomorphic EBV-positive B-cell LPDs may arise in association with the tyrosine kinase inhibitor imatinib, while EBV-positive reactive follicular hyperplasias and HHV8-negative effusion-based lymphomas are described in patients receiving dasatinib.[278,303-305] Aggressive B-cell and T-cell lymphomas are also reported in patients receiving JAK inhibitor therapy.[279,280] Although data is limited, at least a subset of these reported LPDs have shown regression after a withdrawal of therapy.[278,303,305] Fludarabine has been associated with the development of EBV-associated LPDs, most frequently in patients receiving treatment for a low-grade lymphoma.[275,276] The

association between fludarabine therapy and LPD is more difficult to prove than with methotrexate because of the presence of a preexisting LPD and the difficulty encountered in reversing the immune defect.[306,307] The cases of EBV-positive LPD after fludarabine therapy include polymorphic B-cell LPDs, monomorphic B-cell lymphomas, and CHL-like proliferations; some do regress without antineoplastic therapy.[275,276,306,307] It is important in these cases to rule out a Richter-like transformation of the original neoplasm. EBV-positive LPD may also follow the use of other chemotherapeutic regimens, such as the LPD resembling lymphomatoid granulomatosis reported in a small number of children and rare adults after therapy for acute lymphoblastic leukemia.[271,308,309]

Pearls and Pitfalls

- Iatrogenic immunodeficiency-associated lymphoproliferative disorders (LPDs) are best described in patients after solid organ or allogeneic hematopoietic stem cell transplantation; in patients with rheumatoid arthritis after methotrexate therapy; and in young men with Crohn's disease treated with infliximab (and azathioprine or mercaptopurine). They can also occur after immunosuppression/immunomodulatory agents or immunosuppressive chemotherapeutic regimens in many other circumstances.
- Diagnosis of a posttransplant lymphoproliferative disorder (PTLD) rests heavily on the history of a prior transplantation;

however, not every lymphoid proliferation in a transplant patient is a PTLD.

- Recognition of a PTLD is extremely important for clinical purposes, even if categorization is problematic. Absolute distinction between a “benign” and a “malignant” PTLD can be more of a philosophic problem than a practical one. Nondestructive PTLD can be fatal, and lymphoma-like lesions may regress with decreased immunosuppression. Small tissue biopsies may preclude a precise classification.
- Presence of a clonal lymphoid population does not indicate that a PTLD is a “lymphoma” type and should not be considered pathognomonic of PTLD.
- Patients with a nondestructive PTLD may have a polymorphic or monomorphic PTLD at other sites.
- Synchronous and metachronous PTLDs may or may not be clonally related.
- Before diagnosing a polymorphic PTLD, exclude a possible monomorphic T-cell PTLD, because morphologically, the latter may be very polymorphic.
- Even if not required for the diagnosis, the finding of numerous EBV-positive cells is very helpful in making the diagnosis of an iatrogenic immunodeficiency-associated LPD; however, their absence does not rule out the diagnosis, and the presence of small numbers of positive cells is not pathognomonic. EBV-positive cases should be distinguished from EBV-negative cases.

- Transplant patients can show both allograft rejection and PTLD at the same time.
- Always inquire about the use of immunosuppressive/immunomodulatory agents before diagnosing an overt lymphoma in patients with preexisting disorders that are often treated with these agents, such as rheumatoid arthritis.

Nonlymphoid Malignancies That Mimic Lymphomas

Metastatic Tumors

Systemic Mastocytosis

Bone marrow examination is an important part of the workup of patients with lymphoma. It is often performed for staging purposes and for follow-up to evaluate for response to therapy or recurrence.[1-3] In some patients, a diagnosis of lymphoma is initially made on a bone marrow biopsy obtained for evaluation for unexplained cytopenias, fevers of unknown origin, unexplained organomegaly, or mass lesions difficult to access for biopsy.[4,5]

Evaluation of bone marrow involvement by lymphoma can be challenging, particularly in patients without a prior diagnosis at an extramedullary site. For example, benign lymphoid infiltrates are frequently encountered in the bone marrow core biopsies in older individuals or patients with autoimmune diseases, and can be difficult to distinguish from lymphoma, even with the help of ancillary techniques.[6,7] In patients with an established diagnosis of lymphoma, the assessment of bone marrow involvement can be complicated by situations such as a discordant histologic type in the bone marrow compared with the extramedullary lesion.[8,9] Additionally, subclassification of lymphoma based on the bone

marrow findings is not always straightforward and requires not only the knowledge of the diagnostic features of various lymphoma subtypes but also the appropriate use of ancillary techniques. It is also important to recognize the limitations of classification of lymphoma based on bone marrow findings alone; biopsy of extramedullary lesions may be required.

The core biopsy is usually the most informative when evaluating bone marrow involvement by lymphoma. However, peripheral blood smear, bone marrow aspirate smear, particle clot section, and touch imprint also provide valuable complementary information and may be diagnostic in themselves. Therefore, all these preparations should be examined together and the findings correlated. An adequate bone marrow sampling is important to ensure the detection of focal lymphomatous infiltrates. It is recommended that the bone marrow core biopsy should be at least 1.5 to 2 cm long; the yield of lymphoma detection is significantly higher with bilateral than unilateral core biopsies (**Fig. 55-1**).[10,11] Additionally, sections from multiple levels of the core biopsy should be examined in order to increase the detection rate. However, significant advances in PET imaging methodology have nearly obviated the need for routine staging marrow biopsies for diffuse large B-cell lymphoma (DLBCL) and Hodgkin lymphoma (HL) in cases with PET-positive disease in the marrow.[12,13]

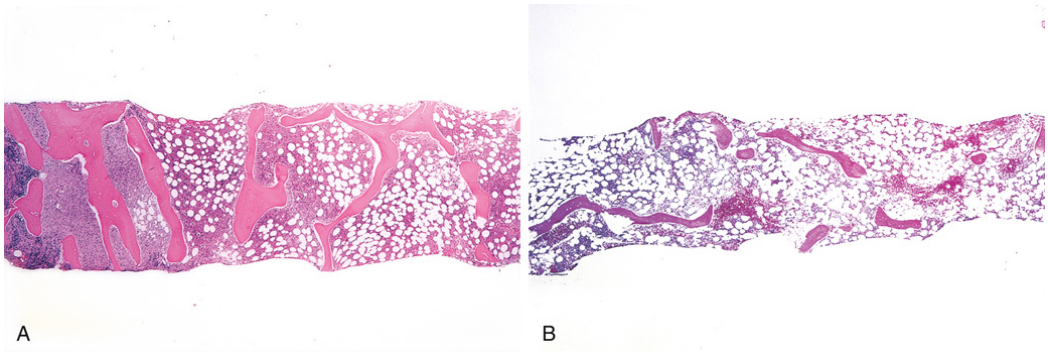

FIGURE 55-1 Bilateral bone marrow core biopsy obtained for staging purposes from a patient with diffuse large B-cell lymphoma.**A,** Only the *left side* core biopsy specimen is involved by lymphoma. The lymphomatous infiltrate is focal (involving only the left side of the core) but exhibits a diffuse growth pattern. **B,** The *right side* core biopsy specimen is uninvolved.

Flow cytometric immunophenotyping, immunohistochemistry, cytogenetic analysis, and molecular testing are important in evaluation of bone marrow specimens for lymphoma, and should be used in a logical and cost-effective way based on the morphologic findings and clinical setting. Whenever ancillary techniques are employed, the results should be correlated with one another and with the morphologic findings. It is also worth noting that knowledge of each technique, including its limitations, is important in effective utilization of these techniques in bone marrow evaluation of lymphoma.

This chapter focuses on the distinction between benign and lymphomatous infiltrate and morphologic features of various

subtypes of lymphoma in the bone marrow. In addition, nonlymphoid lesions mimicking lymphoma in the bone marrow are briefly discussed.

Distinction Between Benign Lymphoid Aggregates and Lymphoma

Benign lymphoid aggregates frequently occur in the bone marrow in older individuals, as well as in various reactive conditions, such as systemic autoimmune disorders (rheumatoid arthritis, lupus, autoimmune hemolytic anemia, idiopathic thrombocytopenia, and Hashimoto thyroiditis), aplastic anemia, viral infection (HIV and hepatitis), and myeloproliferative neoplasms (MPNs) and myelodysplastic syndromes (MDSs).[6,14,15]

Morphology

The assessment of lymphoid infiltrates in the bone marrow is first based on the morphologic findings. However, other studies such as immunohistochemistry, flow cytometric immunophenotyping, or molecular analysis may be required for further evaluation. Although these techniques are usually informative, the nature of the lymphoid infiltrate may remain unknown in some cases. The extent of testing to analyze a lymphoid infiltrate in the bone marrow depends on the clinical setting and the degree of suspicion for lymphoma. Several morphologic features can be used in distinguishing benign lymphoid aggregates from lymphoma (**Table 55-1**).[6,7]

Benign lymphoid aggregates are usually single or few in number, small in size, well circumscribed, random, and nonparatrabecular (**Fig. 55-2**). The cells within the aggregates are often polymorphous

and may include plasma cells and histiocytes. Reactive germinal centers may be present, which are more commonly seen in patients with autoimmune diseases. However, germinal centers are not exclusively seen in benign lymphoid infiltrates; non-Hodgkin lymphomas, particularly splenic marginal zone lymphoma (SMZL), may also contain reactive germinal centers in the bone marrow (see **Fig. 55-15**).[16] Additionally, lipogranulomas are often seen in the marrow and should not be confused with infectious granulomas or HL. These are, however, foamy and lymphocyte poor, allowing their distinction from other allied entities and lymphomas (**Fig. 55-3**).

In contrast to benign lymphoid aggregates, lymphomatous aggregates are more frequently multiple, larger in size, and have infiltrative borders. Paratrabecular lymphoid infiltrates are almost always neoplastic and most frequently associated with follicular lymphoma (FL), although this pattern is by no means exclusive to FL.[6,17] The presence of distinct intrasinusoidal lymphoid infiltrates is usually an indication of a neoplastic process and most commonly seen in SMZL, splenic diffuse red pulp small B-cell lymphoma (SDRPSBCL), intravascular large B-cell lymphoma, and hepatosplenic T-cell lymphoma.[18,19] Neoplastic lymphoid infiltrates generally exhibit a more homogeneous cellular composition than benign lymphoid infiltrates. However, a polymorphous infiltrate also characterizes some subtypes of lymphomas, most notably peripheral T-cell lymphoma and HL.[14,20] Importantly, the presence of morphologically abnormal lymphocytes and architectural features in the bone marrow core biopsy, such as paratrabecular localization and infiltrative borders, should raise the suspicion of a neoplastic process.

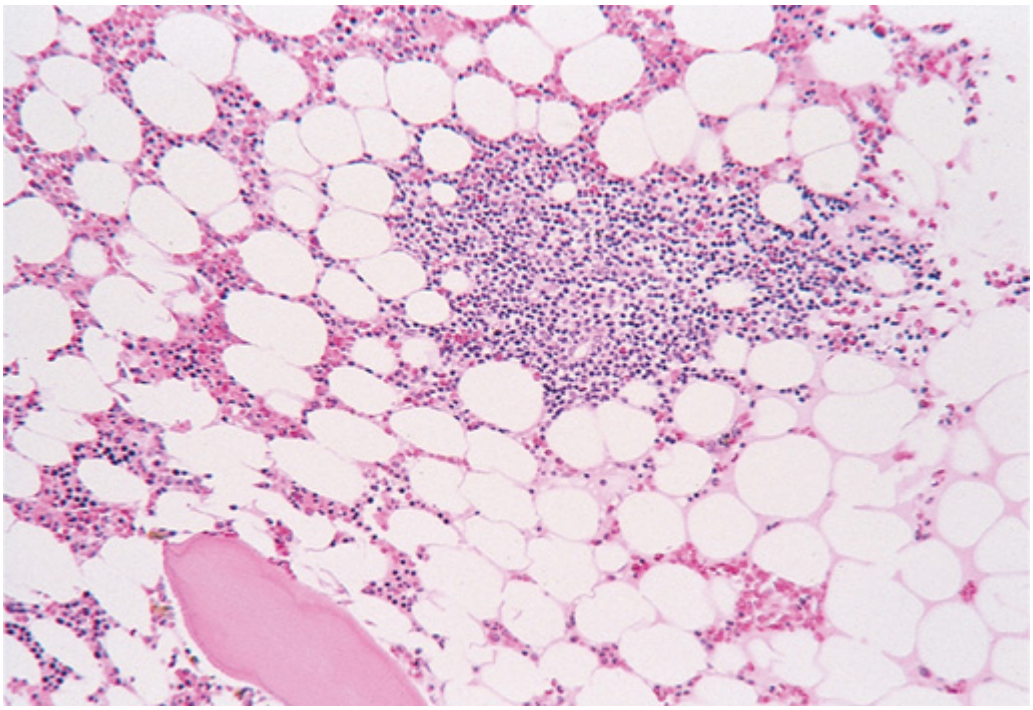

FIGURE 55-2 Benign lymphoid aggregate in a bone marrow core biopsy.The single lymphoid aggregate is small, well circumscribed, located between bony trabeculae, and composed predominantly of small, mature-appearing lymphocytes. A small blood vessel is present in the lymphoid aggregate.

Table 55-1

Features Distinguishing Benign Lymphoid Aggregates From Lymphoma in Bone Marrow Biopsy

Benign	Malignant
Aggregates are few in number	Aggregates are variable in number and may be multiple
Aggregates with random distribution	Paratrabecular aggregates may be present
Aggregates are usually round, well-circumscribed	Aggregates are often irregularly shaped with infiltrative borders
Polymorphous cellular compositions	Usually homogeneous cellular composition except for some peripheral T-cell lymphomas and Hodgkin lymphoma; atypical cytologic features may be present
Intrasinusoidal infiltrates usually absent	Intrasinusoidal infiltrates may be present
Vascularity is often prominent	Vascularity is usually not prominent except in

Benign	Malignant
	peripheral T-cell lymphomas
Benign germinal centers are occasionally present	Benign germinal centers are not present except for marginal zone lymphomas
No morphologically abnormal lymphocytes in bone marrow aspirate smears or imprints	Morphologically abnormal lymphocytes may be present in bone marrow aspirate smears or imprints
Immunohistochemical stains show a mixture of B and T cells, often with T-cell predominance (exceptions occur)	Immunohistochemical stains showing a predominance of B cells, aberrant phenotype, or monoclonal plasma cells suggest B-cell lymphoma; an aberrant T-cell phenotype suggests T-cell lymphoma
No monotypic B-cell population or phenotypically abnormal T-cell population identified by flow cytometry (exceptions occur)	Immunoglobulin light chain restriction or aberrant T-cell phenotype
No monoclonal IGH or TCR gene rearrangement by	Monoclonal IGH or TCR gene rearrangement are often

Benign	Malignant
molecular analysis (exceptions occur)	identified by molecular analysis

Immunohistochemistry

A panel of immunohistochemical stains on the bone marrow core biopsy or particle clot section is often required to assist in the distinction between benign versus neoplastic lymphoid infiltrates. Immunohistochemical stains for B-cell markers (e.g., CD20, PAX5) and T-cell markers (e.g., CD3) are often used to determine the proportions of B and T cells within the lymphoid aggregates. Rarely, a cluster of plasmacytoid dendritic cells may resemble a lymphoid aggregate (**Fig. 55-4**), and appropriate immunohistochemical stains will help distinguish these from benign lymphoid aggregates. Benign lymphoid aggregates usually have a mixture of B and T cells, and T cells frequently predominate, whereas lymphoid infiltrates composed primarily of B cells, especially if multiple, are often neoplastic. However, some B-cell lymphomas may be accompanied by a significant number of reactive T cells, such as FL and T-cell/histiocyte-rich large B-cell lymphoma. Therefore, a mixture of B and T cells or a predominance of T cells in the lymphoid infiltrate does not completely exclude a diagnosis of B-cell lymphoma.[21]

Similar to extramedullary lymphomas, demonstration of an aberrant B-cell or T-cell phenotype by immunohistochemistry, such as expression of CD5 in B cells or loss of pan T-cell antigen in T cells, supports a diagnosis of B-cell or T-cell lymphoma, respectively. Demonstration of immunoglobulin light chain restriction in the plasma cells associated with an atypical B-cell infiltrate supports a

diagnosis of B-cell lymphoma with plasmacytic differentiation, such as marginal zone lymphoma (MZL), lymphoplasmacytic lymphoma, and the more recently recognized primary cold agglutinin disease.[22] Immunohistochemical stains for markers associated with specific subtypes of lymphoid neoplasm, such as cyclin D1 in mantle cell lymphoma (MCL) and hairy cell leukemia (HCL), CD30/ALK1 in anaplastic large cell lymphoma, and LEF1 in chronic lymphocytic leukemia (CLL)/small lymphocytic lymphoma (SLL) (**Fig. 55-5**) not only help with diagnosis, but also subclassification and sometimes prognosis of lymphomas.

Special consideration should be given to patients who have been treated with an anti-CD20 agent and continue to exhibit lymphoid infiltrates in the bone marrow. In some cases, the lesions represent residual lymphoma, while in others, the lymphoma has likely been eliminated by anti-CD20 therapy, resulting in lymphoid infiltrates that are composed entirely of CD3-positive T cells.[23] These aggregates may mimic residual lymphoma because they can be large, multiple, or even paratrabecular (**Fig. 55-6**). When residual B-cell lymphoma remains in the bone marrow of patients treated with anti-CD20 therapy, immunohistochemical stains or flow cytometric immunophenotyping using B-cell markers other than CD20 (e.g., CD79a, PAX5) are necessary to evaluate post-therapy bone marrow.

It is also worth noting that in the early course of granulocyte colony-stimulating factor (G-CSF) therapy, the bone marrow frequently shows a marked myeloid shift to immaturity and contains a significant number of promyelocytes, often in a paratrabecular location. The findings may mimic large cell lymphoma (**Fig. 55-7**). Knowledge of the history of G-CSF therapy can aid in the distinction

from lymphoma. If the history is not provided, characteristic changes associated with G-CSF therapy, such as severe toxic changes and a shift to immaturity in granulocytes in the blood and bone marrow aspirate, can also alert one to this possibility. Well-prepared histologic sections that allow observation of the morphologic features of promyelocytes are essential. Immunohistochemical stains for myeloperoxidase, CD20, or CD3 may be required to make the distinction (**Fig. 55-7**).

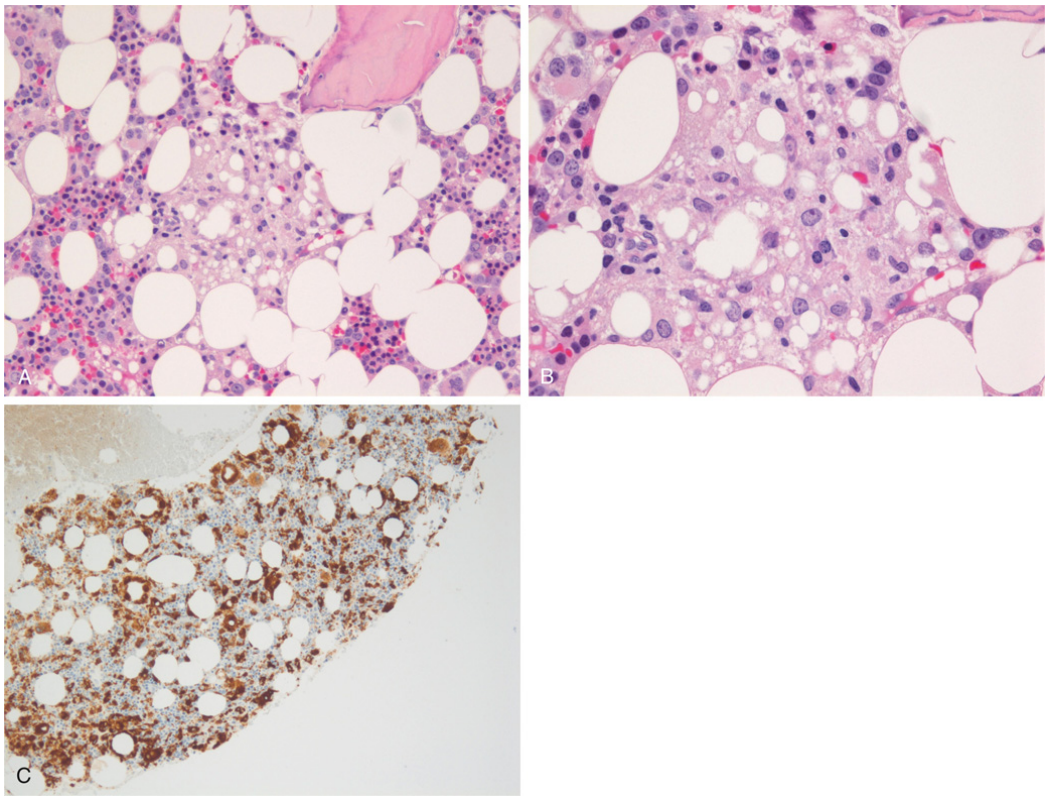

FIGURE 55-3 Lipogranuloma resembling atypical lymphohistiocytic aggregate.**A,** Low-power view showing a discrete cluster in the paratrabecular location. **B,** Higher power shows an admixture of disrupted adipocytes and foamy histiocytes with sparse lymphocytes and no atypical cells. **C,** Immunohistochemical stain for CD68 confirms presence of numerous histiocytes within these aggregates.

Flow Cytometric Immunophenotyping

Flow cytometric immunophenotyping performed on the bone marrow aspirate or peripheral blood is an important part of the workup for bone marrow involvement by lymphoma, and the

correlation with morphology is usually excellent.[24-26] However, discrepancies between the bone marrow core biopsy and the aspirate may occur because of small, focal paratrabecular lesions or bone marrow fibrosis preventing the aspiration of cells; thus a negative flow cytometric result does not exclude the possibility of lymphoma. Flow cytometric immunophenotyping can be performed on a peripheral blood specimen when a bone marrow aspirate is not available, especially if the patient is known to have a lymphoma associated with a higher incidence of peripheral blood involvement, such as CLL/SLL, MCL, SMZL, and lymphoplasmacytic lymphoma (LPL). Occasionally, monotypic B cells are identified by flow cytometry without morphologic evidence of lymphoma. In these cases, it is prudent to evaluate whether the biopsy is of adequate size and quality, and examine multiple levels of sections (**Fig. 55-8**). It may also be appropriate to perform immunohistochemical stains to ensure that a subtle abnormal lymphoid infiltrate is not missed.

It is important to recognize that low levels of monoclonal B cells ($<5.0 \times 10^9$/L) can be identified in the blood in up to 7% of older individuals who are otherwise healthy and without clinical or morphologic evidence of lymphoma.[27-29] This finding is termed *monoclonal B lymphocytosis (MBL)*. MBL usually exhibits a CLL-like phenotype (CD5 positive, CD23 positive). Most patients with MBL also have lymphoid aggregates in the bone marrow, but they are not regarded as diagnostic for lymphoma.[30] Small monoclonal B-cell populations can also be initially identified in the bone marrow aspirate in patients without evidence of lymphoma, and these monoclonal B-cell populations are more commonly CD5-negative than MBL in the peripheral blood.[31] In these CD5-negative cases, as

well as cases with MCL-like phenotype, clinical and laboratory workup may be indicated to rule out lymphoma. Occasionally, aberrant T-cell populations of unclear significance can also be identified by flow cytometry in patients without evidence of lymphoma.[32] These findings emphasize the importance of correlating immunophenotypic results with the clinical and morphologic findings in bone marrow evaluation.

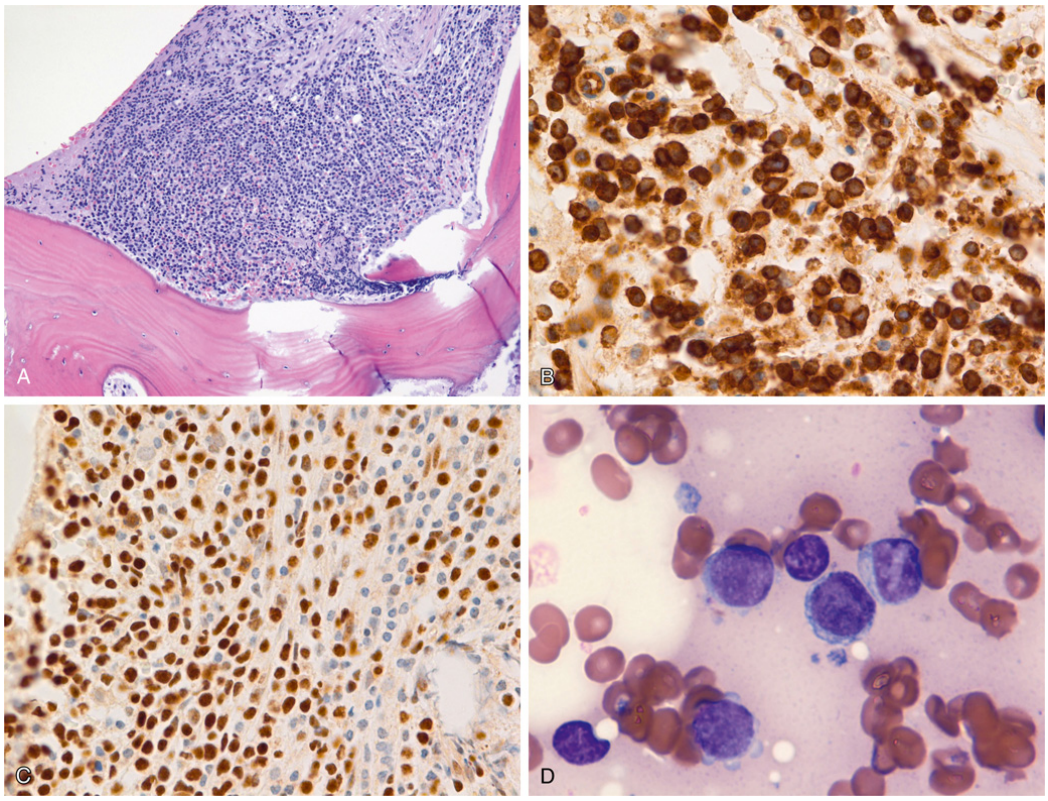

FIGURE 55-4 Plasmacytoid dendritic cells resembling lymphoid aggregate.**A,** Paratrabecular aggregate of lymphoid-appearing cells with infiltrative borders. **B–C,** Immunohistochemical stains for CD123 **(B)** and TCF4 **(C)** are both strongly positive in the atypical cells, confirming that these are plasmacytoid dendritic cells in a patient with treated blastic plasmacytoid dendritic cell neoplasm. **D,** Aspirate smears (Wright-Giemsa stain) show scattered plasmacytoid dendritic cells, which often have circumferential microvacuolations. Note the medium size of the

atypical cells compared with the two small lymphocytes in the background.

Molecular Diagnostic Studies

Molecular analysis plays an important adjunctive role, especially in cases where morphologic and immunohistochemical findings are uncertain.[33-38] Polymerase chain reaction (PCR) for immunoglobulin heavy chain (IGH) or T-cell receptor (TCR) gene rearrangement on paraffin-embedded bone marrow tissue or fresh aspirate is typically used to aid in the differentiation of benign versus neoplastic lymphoid infiltrate.

Clonal IGH or TCR gene rearrangements have been reported in about 65% to 85% and 60% to 70% of bone marrow specimens with morphologic and immunohistochemical evidence of B-cell or T-cell lymphoma, respectively.[33-35] Clonal IGH gene rearrangement has also been identified in about 15% to 65% of cases interpreted as suspicious for lymphoma and 10% to 40% of cases without morphologic evidence of lymphoma. Of importance, clonal TCR gene rearrangements were reportedly identified in morphologically negative bone marrow in over half of patients diagnosed with T-cell lymphomas.[36,38] Interestingly, one study reported that a clonal T-cell population was identified in about 13% of B-cell lymphomas and a clonal B-cell population in about 3% of T-cell lymphomas in the bone marrow.[34] It is also important to be aware that clonal B-cell or T-cell populations may be present in various reactive conditions such as inflammatory diseases, autoimmune disorders, and post–stem cell transplant.[39,40] Therefore, the results of molecular studies should be interpreted in context and correlated with additional information

because monoclonality is not synonymous with malignancy, and failure to detect monoclonality does not rule out a lymphoma. Some molecular studies are important not only for distinguishing benign versus neoplastic process but also for subclassification and prognosis of certain lymphomas, such as assessment of *MYD88* and *CXCR4* mutations in LPL.[41]

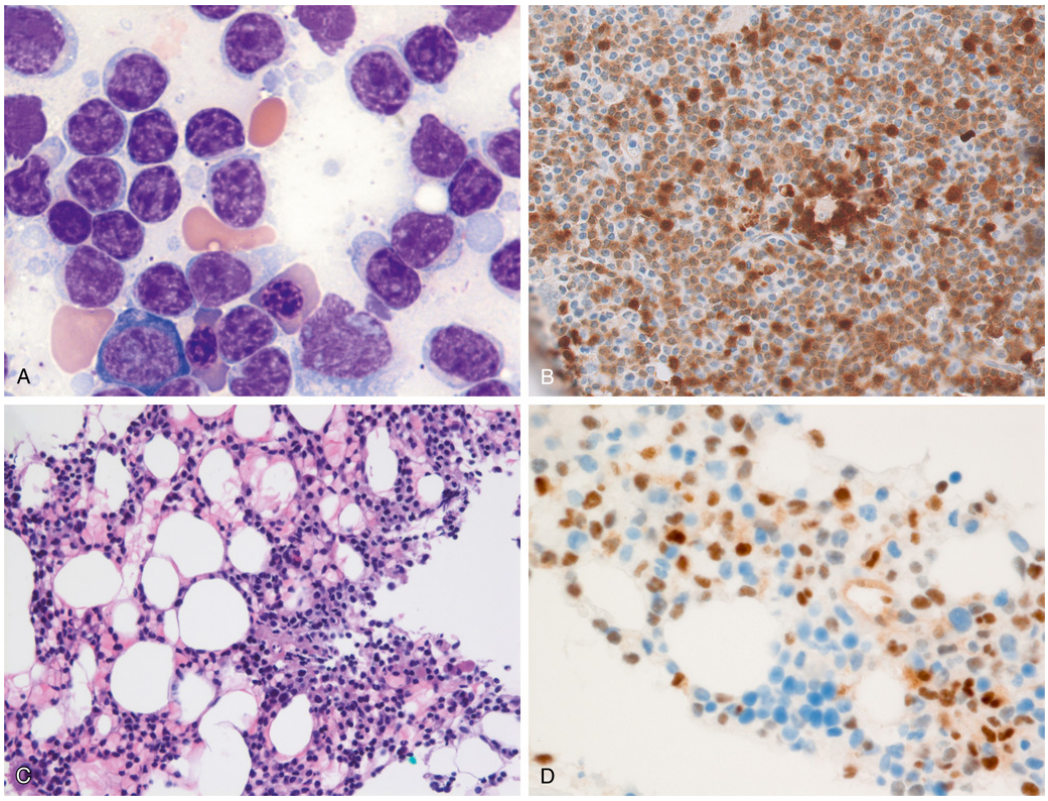

FIGURE 55-5 Diagnostic and prognostic value of immunohistochemical stains on bone marrow biopsy.**A,** Chronic lymphocytic leukemia (CLL) cells in the bone marrow aspirate smear. **B,** Immunohistochemical stain for ZAP70 on the bone marrow core biopsy of the same case shows weak staining in the CLL cells while a cluster of normal T cells in the center of the field shows strong ZAP70 staining that serves as an internal positive control. **C,** Seemingly normocellular marrow without apparent atypical lymphoid infiltrate in a patient with hairy cell leukemia. **D,** Immunostain for CD20 (not shown) highlights the abnormal infiltrate that is positive for cyclin D1, confirming the diagnosis. In addition to

mantle cell lymphoma, cyclin D1 is positive in the majority cases of hairy cell leukemia and a subset of multiple myeloma cases. Normal endothelial cells and histiocytes service as internal positive controls for cyclin D1. Most bone marrow immunohistochemical stains have background internal control cells, which are probably the most appropriate cells to assess quality of staining.

Non-Hodgkin Lymphoma Involving Bone Marrow

Incidence of Bone Marrow Involvement

Bone marrow involvement by lymphoma represents stage IV disease based on the Ann Arbor lymphoma staging system.[1] The overall incidence of lymphoma involving the bone marrow is 35% to 50%.[14] However, there is considerable variability for different lymphoma subtypes. In general, indolent lymphoma, highly aggressive lymphoma, and the majority of peripheral T-cell lymphomas involve the bone marrow with high frequency. For example, FL, CLL/SLL, and MCL involve the bone marrow in up to 60%, 85%, and 90% of cases, respectively[14,42,43]; Burkitt lymphoma (BL) in about 30% to 60% of cases[14]; and DLBCLs in 20% to 30% of cases.[44,45]

The incidence of bone marrow involvement by specific subtypes of peripheral T-cell lymphomas has a wide range.[46,47] For example, virtually all hepatosplenic T-cell lymphoma and up to 70% of angioimmunoblastic T-cell lymphomas involve the bone

marrow.[48,49] Anaplastic large cell lymphoma and extranodal natural killer (NK)/T-cell lymphoma, nasal type, involve the bone marrow in approximately 10% to 30% and 10% to 20% of cases, respectively.[46,47,50] Primary cutaneous T-cell lymphomas, such as mycosis fungoides (MF), are generally considered to spare the bone marrow until advanced stage. However, careful examination identifies marrow involvement in approximately 22% of patients with cutaneous T-cell lymphoma at diagnosis.[51]

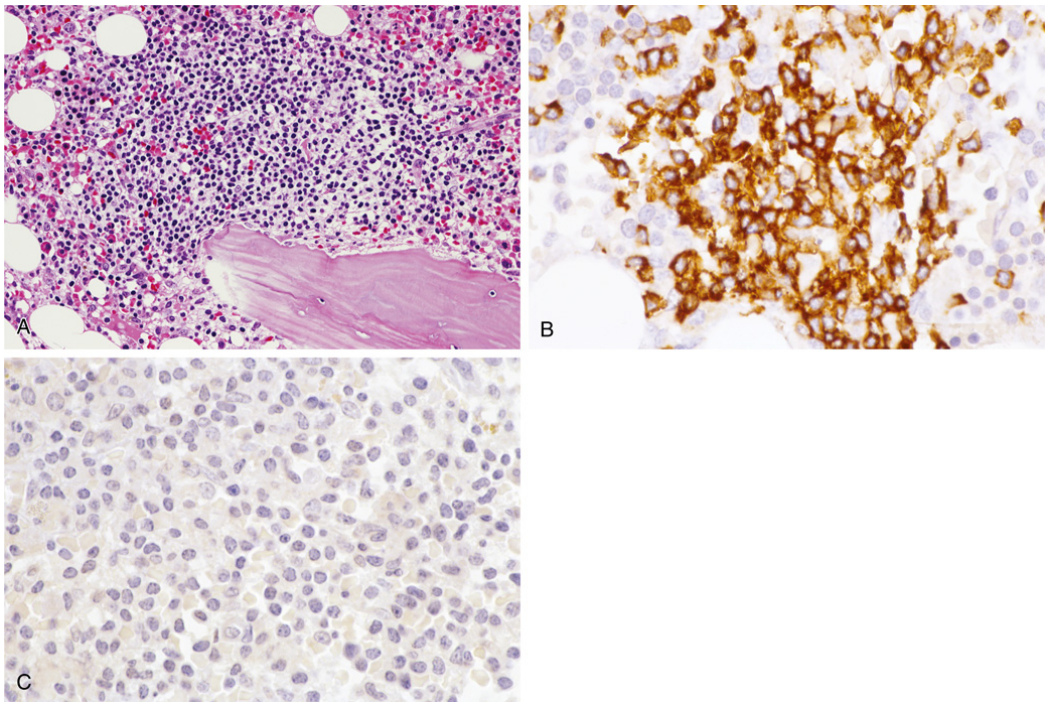

FIGURE 55-6 Paratrabecular lymphoid aggregate in bone marrow after rituximab therapy.**A,** This paratrabecular lymphoid aggregate after rituximab treatment for low-grade follicular lymphoma (FL) is composed of small lymphocytes, with rare histiocytes and stromal cells, mimicking residual FL. **B,** Immunohistochemical staining for CD3 shows that the lymphocytes are virtually all CD3-positive T cells. **C,** Immunohistochemical stains for PAX5 and CD79a (not shown) are both completely negative. Therefore, the lymphoid aggregate does not represent residual FL.

Histologic Patterns of Bone Marrow Involvement

Non-Hodgkin lymphomas infiltrate the bone marrow in a variety of architectural patterns (**Table 55-2**), and more than one pattern is often seen in an individual patient.[9,10,17] Knowledge of these features is helpful in identifying neoplastic lymphoid infiltrates and in some cases facilitates lymphoma classification.

Lymphomatous infiltrates in the bone marrow can occur in five different patterns: focal random (nodular), focal paratrabecular, interstitial, diffuse, and intrasinusoidal (**Fig. 55-9**). Focal infiltrates are the most common and characterized by discrete collections of neoplastic lymphocytes. Even though they focally displace bone marrow and fat cells, they are usually associated with considerable sparing of normal hematopoietic tissue. Focal infiltrates are present in either random or paratrabecular locations. Focal random lymphoid infiltrates occupy space away from the bony trabeculae, whereas paratrabecular infiltrates preferentially grow along and "hug" the bony trabeculae. Random lymphoid infiltrates that expand and focally abut the bone are not considered paratrabecular. In interstitial infiltrates, the neoplastic lymphocytes infiltrate between normal hematopoietic cells without significantly disrupting the bone marrow architecture. They usually do not replace large amounts of bone marrow tissue, even though there is generally widespread bone marrow involvement. Diffuse infiltrates completely replace the hematopoietic elements between the bony trabeculae in a portion or all of the bone marrow core biopsy section. Intrasinusoidal infiltration is characterized by collections of neoplastic lymphocytes within the sinusoids; these infiltrates are typically subtle and difficult to appreciate on hematoxylin and eosin (H&E)–stained sections but can be highlighted by immunohistochemical stains.

B-Cell Lymphomas Involving Bone Marrow

This section describes the characteristics of selected subtypes of B-cell lymphomas with emphasis on the morphologic features specific to bone marrow involvement. Other features such as immunophenotype and molecular cytogenetic features are briefly discussed, and more details can be found in the specific chapters on the disease entities.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

CLL is the leukemic manifestation, and SLL is the tissue counterpart of the same disease process. About 85% of patients with CLL/SLL have bone marrow involvement at diagnosis; rarely, patients may have isolated bone marrow involvement.[14,42] The patterns in which CLL/SLL infiltrates the bone marrow are focal random (**Fig. 55-10**), diffuse, interstitial, or mixed, and sometimes admixed with a transformed large cell component. Although focal random infiltrates can expand to touch the bony trabeculae, distinctly paratrabecular infiltrates are absent. When paratrabecular infiltrates are observed, the diagnosis of CLL/SLL should be questioned, and other types of lymphoma, such as FL and MCL, should be considered in the differential diagnosis. The neoplastic lymphocytes are small with round nuclei, condensed chromatin, and scant cytoplasm. Proliferation centers, the characteristic morphologic finding of CLL/SLL in lymph node tissue, are occasionally encountered in the bone marrow core biopsy (**Fig. 55-11**).

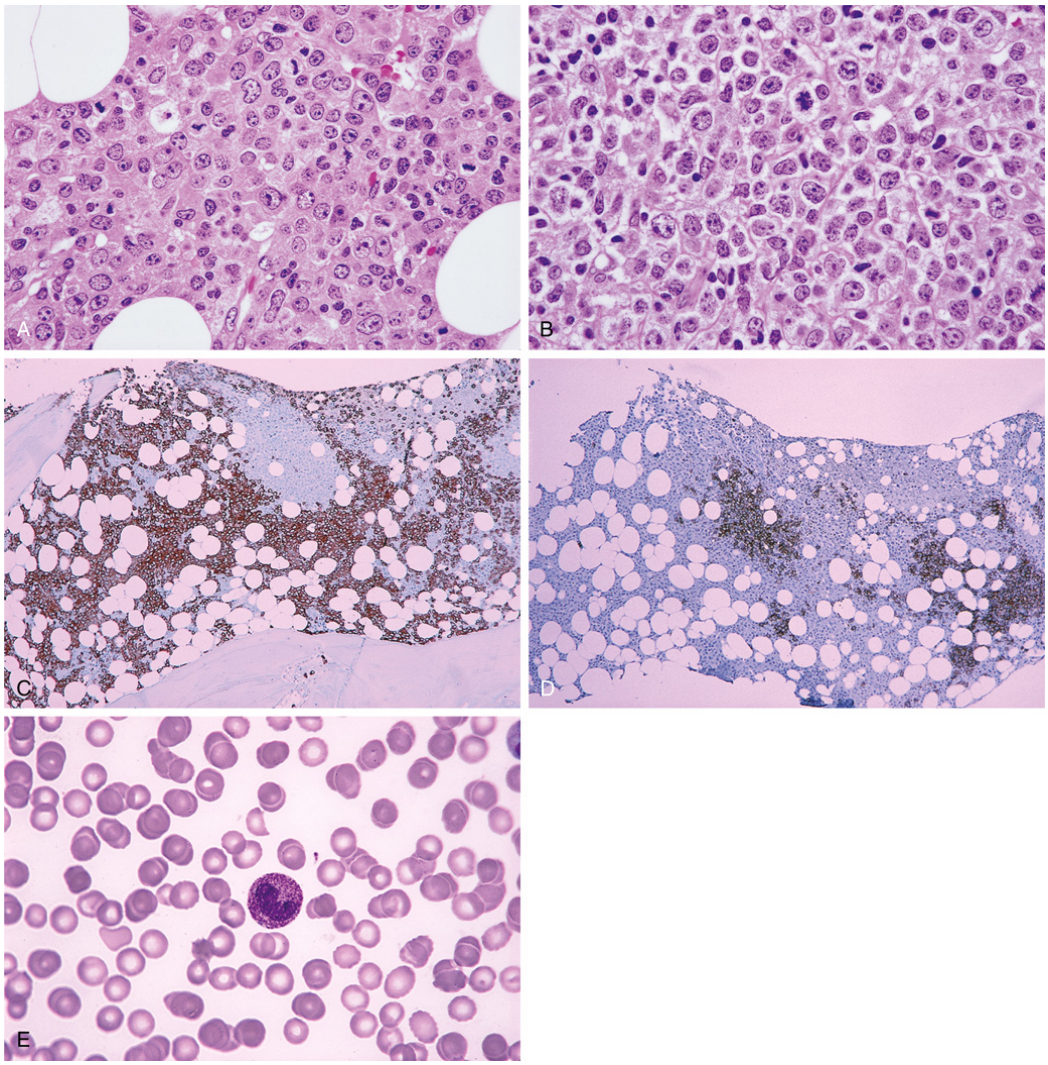

FIGURE 55-7 Bone marrow with residual large B-cell lymphoma and increased numbers of promyelocytes secondary to growth factor therapy.**A,** Sheets of promyelocytes in a hematoxylin and eosin (H&E)-stained bone marrow core biopsy. **B,** Large B-cell lymphoma in another area of the bone marrow biopsy. The promyelocytes and lymphoma cells closely resemble each other morphologically and pose diagnostic confusion. **C,** Immunohistochemical

staining for myeloperoxidase highlights the promyelocytes. **D,** Immunohistochemical staining for CD20 highlights the lymphoma cells (note patchy multifocal infiltrative pattern supporting lymphoma). **E,** Neutrophil with prominent toxic granules and Döhle body because of colony-stimulating factor therapy.

The CLL/SLL is typically $CD19^+$, dim $CD20^+$, $CD5^+$, $CD10^-$, $CD23^+$, $FMC7^-$/dim^+, $CD79b^-$/dim^+, $CD200^+$, and dim surface immunoglobulin light chain restricted. Some cases of CLL/SLL may have overlapping morphologic and immunophenotypic features with MCL; however, negative immunohistochemical stains for cyclin D1 and SOX11 essentially rule out the latter possibility. CD200, an immunoglobulin superfamily membrane glycoprotein, is found to be highly expressed in virtually all cases of CLL/SLL but absent or expressed at a low level in MCL. Thus positive staining for CD200 by flow cytometry helps distinguish CLL/SLL from MCL; however, it does not help the differential diagnosis between CLL/SLL from other B-cell lymphoproliferative disorders.[52] The nuclear overexpression of lymphoid-enhancer-binding factor 1 (LEF1) has also been found to be highly associated with CLL/SLL among small B-cell lymphomas and serves as a reliable immunohistochemical marker to differentiate CLL/SLL from other small B-cell lymphomas, including MCL and CD5-positive MZL (**Fig. 55-12**).[53-56] Care must be taken in interpreting cases with frequently admixed T cells, as LEF1 is normally expressed in the T cells.

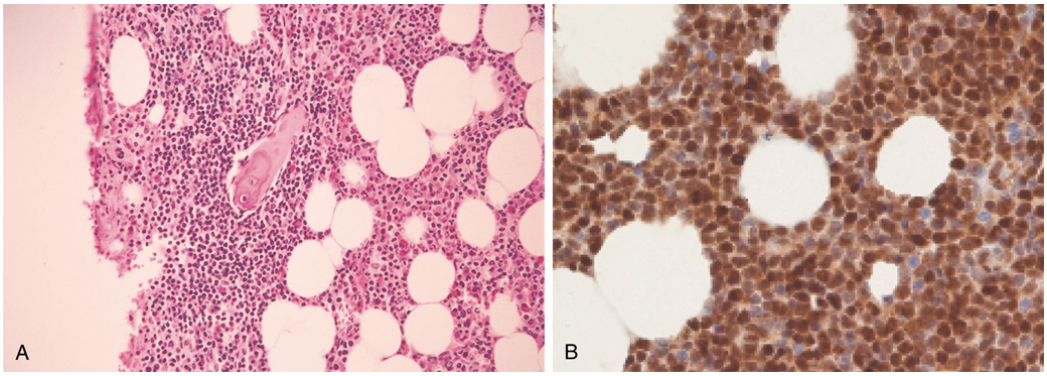

FIGURE 55-8 Mantle cell lymphoma (MCL) identified in the deeper section of bone marrow core biopsy from a patient with an established diagnosis of MCL.**A,** The initial bone marrow sections were negative for lymphoma. Deeper sections were obtained because CD5-positive monotypic B cells were identified by flow cytometry. Lymphoma cells were identified in the deeper sections surrounding a bony trabecula and infiltrating between fat cells. Flow cytometry is especially useful in MCL, and positive staining for cyclin D1 and SOX11 is valuable when flow cytometry immunophenotyping is not available. **B,** This image is from a different case demonstrating positive SOX11 staining in MCL.

* The common patterns are listed; patterns may be mixed.

Lymphoplasmacytic Lymphoma and Waldenström Macroglobulinemia

LPL is a B-cell neoplasm that commonly involves the bone marrow and, less frequently, lymph nodes. Most LPLs in the bone marrow represent Waldenström macroglobulinemia (WM), which is defined as LPL with bone marrow involvement and a serum IgM monoclonal protein of any concentration.[57,58] LPL infiltration in the bone marrow is commonly in a mixed pattern including focal random, paratrabecular, interstitial, or diffuse.[57,59] The infiltrates of LPL/WM consist of small lymphocytes, plasmacytoid lymphocytes, and plasma cells at variable proportions (**Fig. 55-13**). The plasmacytoid lymphocytes are usually in the minority and may be inconspicuous. The number of plasma cells varies considerably, and they are usually a small component of the infiltrate but can be predominant in some cases. The plasma cells are often admixed within the neoplastic lymphoid infiltrate but are occasionally present as small clusters away from the lymphoid aggregates.[60] Intranuclear inclusions (Dutcher bodies) are often identified in the plasma cells (**Fig. 55-13**). Transformed lymphocytes with distinct nucleoli may be present, but are usually low in number. Additionally, mast cells and histiocytes are often increased in the bone marrow involved by

LPL. The bone marrow aspirate contains lymphoma cells similar to those in the bone marrow core biopsy; peripheral blood may also be involved, but an absolute lymphocytosis is uncommon.[57,61]

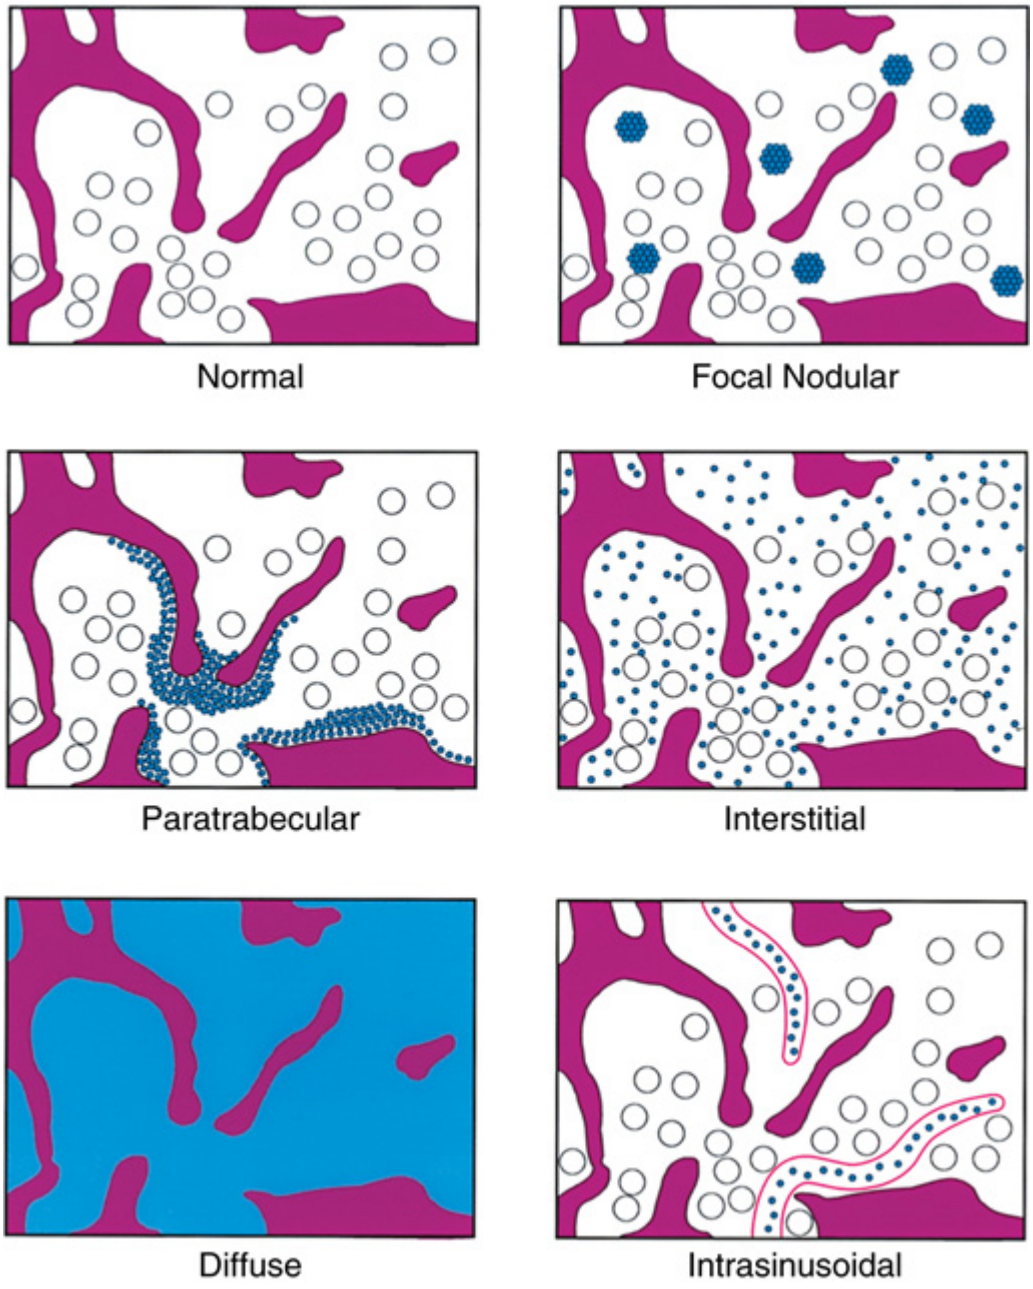

FIGURE 55-9 Diagram illustrating normal bone marrow and the five patterns of infiltration by lymphoma.

LPL is typically $CD19^+$, $CD20^+$, $CD23^-$, $CD5^-$, $CD10^-$, $CD103^-$, surface IgM^+, and surface immunoglobulin light chain–restricted, but expression of CD5 or CD23 may be observed in some cases.[57]

LPL/WM should be distinguished from other B-cell neoplasms with plasmacytic differentiation, such as SMZL. LPL may also mimic plasma cell myeloma when the plasma cell component predominates. The presence of both monotypic B cells and plasma cells with the same light chain restriction, lack of other atypical phenotype in the plasma cells (e.g., CD19 negative, CD56 positive), as well as other clinical and laboratory features such as a serum IgM paraprotein, hyperviscosity, lack of lytic bone lesions, and presence of lymphadenopathy, help distinguish LPL from plasma cell myeloma. The distinction between LPL and SMZL in the bone marrow can be problematic because they share morphologic and immunophenotypic features and occasionally also clinical features.[62] LPL predominantly involves the bone marrow, but may also involve the lymph node or spleen in some cases. SMZL typically exhibits prominent splenomegaly and almost always involves blood and bone marrow, but peripheral lymph nodes are typically not involved. The most distinguishing features of LPL from SMZL in the bone marrow have been reported to include paratrabecular involvement, the presence of lymphoplasmacytic cells, Dutcher bodies, and increased numbers of mast cells,[59] while prominent intrasinusoidal infiltration and reactive germinal centers are more characteristic for SMZL.[63] However, the practical use of these distinguishing features may still be problematic when applied to an individual case.

There are no specific chromosomal abnormalities recognized in LPL.[57] The *MYD88* L265P mutation has been identified in over 90% of patients with LPL/WM; this mutation is uncommon in other B-cell lymphomas, including SMZL. Although not entirely specific,

demonstration of *MYD88* L265P mutation is a valuable adjunct in the diagnosis of LPL/WM.[64]

Marginal Zone Lymphoma

MZL arises from post–germinal center B cells and consists of three distinct diseases: splenic MZL (SMZL), nodal MZL (NMZL), and extranodal MZL of mucosa-associated lymphoid tissue (MALT lymphoma).[65,66]

Splenic Marginal Zone Lymphoma

SMZL is an indolent B-cell lymphoma that typically presents with splenomegaly without lymphadenopathy. Patients may have a small monoclonal serum protein; however, marked hypergammaglobulinemia and hyperviscosity are uncommon.[65,66] SMZL involves the bone marrow and blood in nearly all cases, and the diagnosis is usually made based on the findings of the peripheral blood and bone marrow. The neoplastic cells of SMZL are small-to-medium-sized, with round to slightly irregular nuclei, condensed chromatin, and moderate amounts of pale-blue cytoplasm. Rare large lymphocytes with vesicular nuclei and visible nucleoli, as well as plasmacytoid cells with or without Dutcher bodies, may be admixed among the small neoplastic lymphocytes. Although an absolute lymphocytosis is not a constant feature, neoplastic lymphocytes can often be identified in the blood smears and may show short, polar villi on the cell surface in some cases.

SMZL infiltrates the bone marrow in one or more of the following patterns: intrasinusoidal, interstitial, focal random, and focal paratrabecular; diffuse involvement is uncommon. Intrasinusoidal infiltration is present in the majority of patients, often as one to a few

layers of lymphocytes within the sinusoids (**Fig. 55-14**). This pattern of infiltration is difficult to appreciate on H&E-stained sections but can be highlighted by immunohistochemical staining for B-cell markers. Intrasinusoidal infiltration is not entirely specific for SMZL and may be seen, although often more subtly, in other B-cell lymphomas. Additionally, the presence of reactive germinal centers associated with the neoplastic infiltrate is a feature observed in about 30% of SMZL (**Fig. 55-15**).[63] Immunohistochemical staining for CD21 or CD23 can be used to highlight the follicular dendritic cell meshwork to confirm the germinal center nature of the lymphoid follicles. These reactive germinal centers should not be confused with foci of large cell transformation or neoplastic germinal centers in FL.

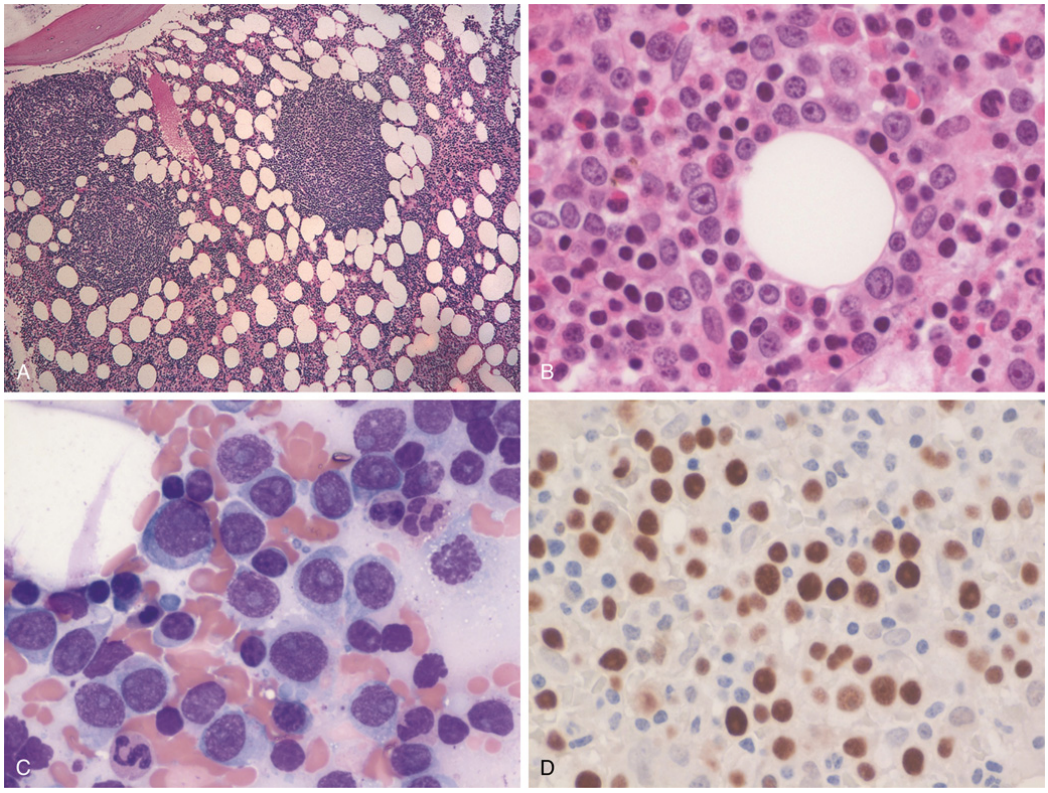

FIGURE 55-10 Chronic lymphocytic leukemia/small lymphocytic lymphoma in bone marrow core biopsy.**A,** Three focal nodular lymphoid infiltrates and interstitial infiltrates are demonstrated in this bone marrow core biopsy section. **B,** Increased numbers of large cells are admixed with the background small lymphocytes. The large cells have prominent nucleoli. **C,** The bone marrow aspirate smear of the same case shows prolymphocytes with centrally located, prominent nucleoli admixed with scattered small chronic lymphocytic leukemia (CLL) cells. **D,** Strong p53 staining is seen in the prolymphocytes

in a patient with prolymphocytic transformation of preexisting CLL.

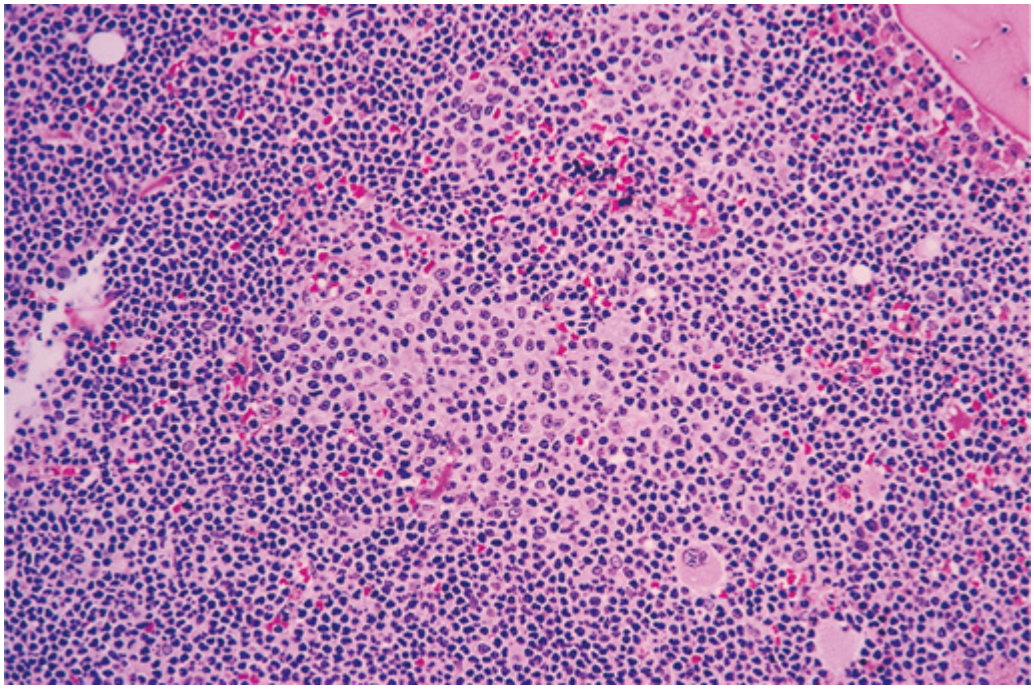

FIGURE 55-11 Proliferation centers of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) in a bone marrow core biopsy.A proliferation center, an ill-defined pale area in the center of the image, in a background of small CLL cells. Proliferation centers contain prolymphocytes with an ample amount of pale cytoplasm and prominent central nucleoli.

SMZL exhibits a “non-specific” immunophenotype, (i.e., $CD19^+$, $CD20^+$, $CD5^-$, $CD10^-$, $CD23^-$, and surface immunoglobulin light chain restriction. This phenotype overlaps with several other B-cell lymphomas, including NMZL and LPL. Additionally, CD5 is positive

in 5% to 10% of cases, CD11c and CD103 in a minority of cases, and CD25 is generally negative.[67-70]

The main differential diagnosis of SMZL in the bone marrow includes SDRPSBCL,[19] LPL, NMZL, and MALT lymphoma. Although the pattern of splenic involvement is distinct between SMZL (white pulp involvement) and SDRPSBCL (diffuse red pulp involvement), separating these two entities on the basis of a bone marrow biopsy is difficult because of overlapping bone marrow histology, immunophenotype, and clinical features. Similar to SMZL, SDRPSBCL uniformly involves the bone marrow, frequently in intrasinusoidal and interstitial patterns. It has been suggested that an exclusive intrasinusoidal infiltration favors SDRPSBCL over MZL.[71] The distinction between SMZL and LPL has been discussed previously under "Lymphoplasmacytic Lymphoma and Waldenström Macroglobulinemia." SMZL also shares similar morphologic features with NMZL in the bone marrow, but intrasinusoidal infiltration is more prominent and reactive germinal centers are more frequent in SMZL than NMZL. Correlation with clinical features is important as SMZL does not involve peripheral lymph nodes or extranodal sites, in contrast to NMZL, and is often associated with HCV, as well as a small paraprotein, and hence testing may be appropriate in suspected SMZL.[72]

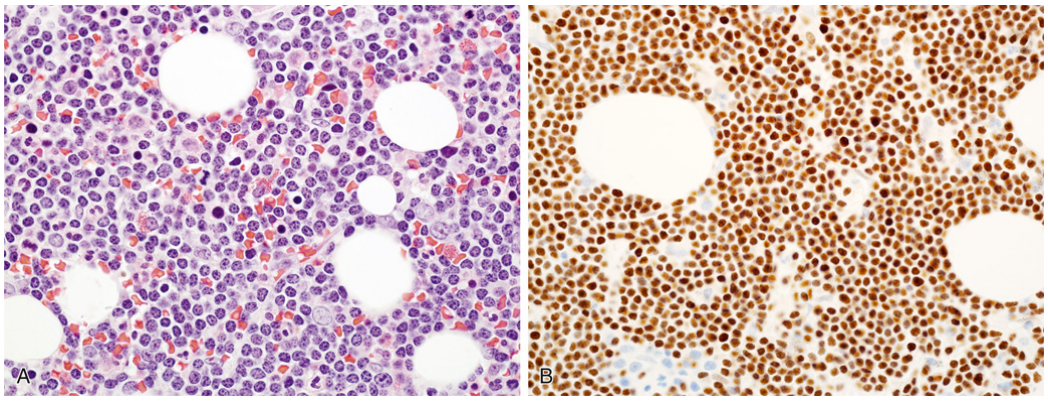

FIGURE 55-12 Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) is positive for lymphoid-enhancer-binding factor 1 (LEF1).**A,** CLL/SLL infiltrates in the bone marrow core biopsy. **B,** Immunohistochemical staining shows strong nuclear staining for LEF1 in CLL/SLL cells.

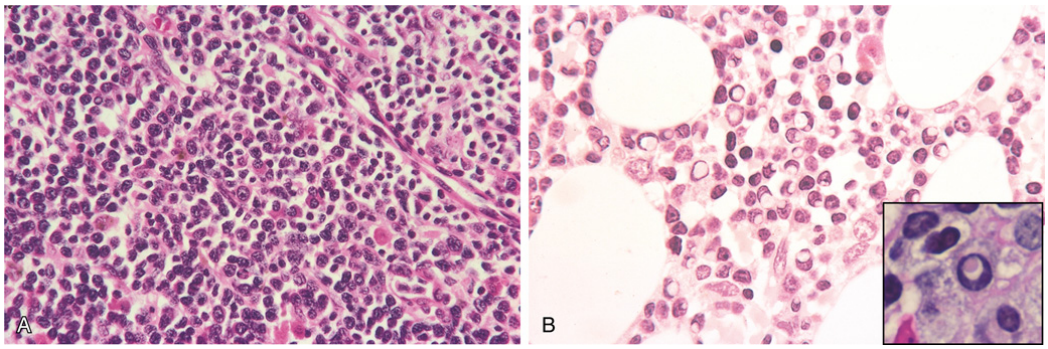

FIGURE 55-13 Lymphoplasmacytic lymphoma in a bone marrow core biopsy.**A,** The infiltrate is dense and contains small lymphocytes, plasmacytoid lymphocytes and plasma cells. **B,** Intranuclear inclusions (Dutcher bodies; *inset*) in the plasma cells are evident in this case.

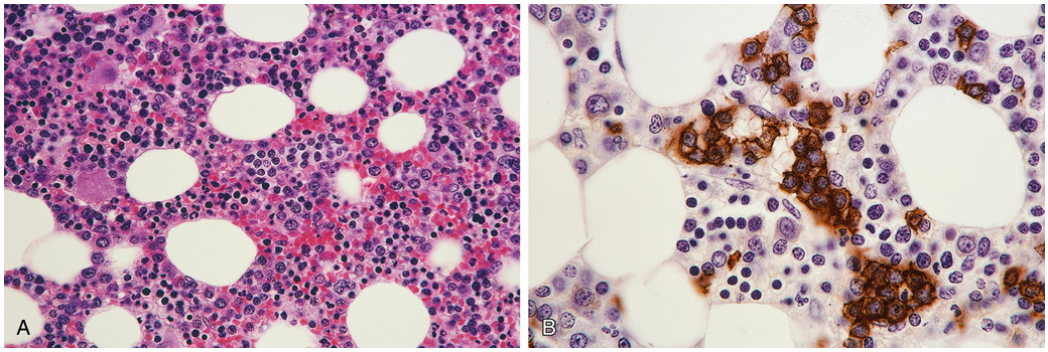

FIGURE 55-14 Splenic marginal zone lymphoma in a bone marrow core biopsy.**A,** The infiltrate blends in with the normal hematopoietic elements and is difficult to identify on the H&E-stained section in this case. **B,** Immunohistochemical staining for CD20 highlights the lymphoma cells with focal intrasinusoidal infiltration.

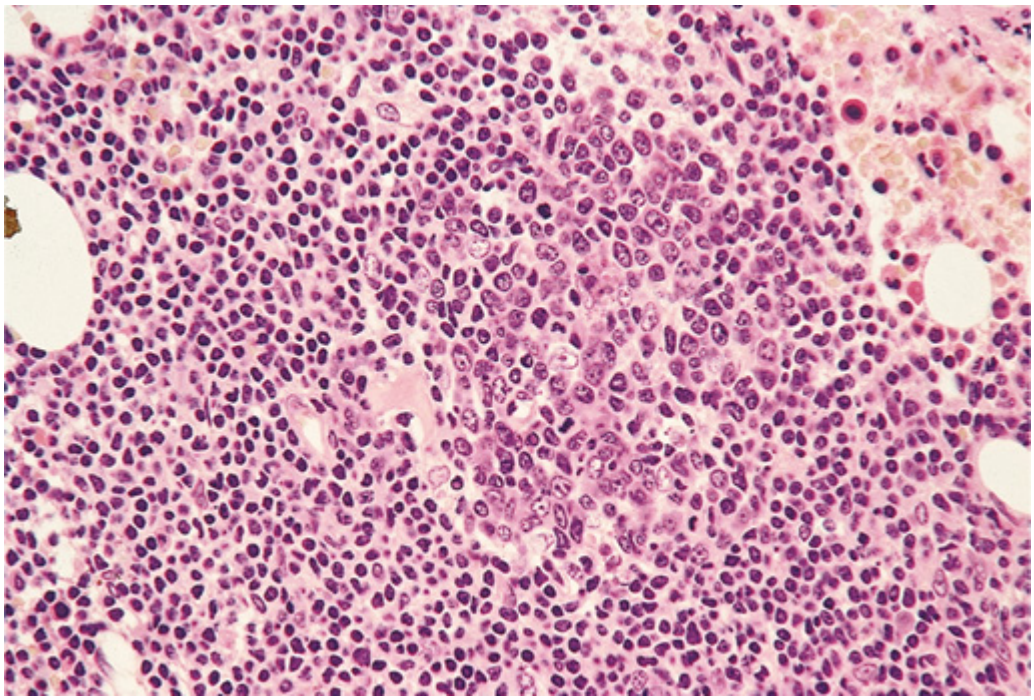

FIGURE 55-15 Splenic marginal zone lymphoma in a bone marrow core biopsy.Most of the lymphoma cells are small, with slightly irregular nuclei. A reactive germinal center is present in the neoplastic infiltrate.

When villous lymphocytes are present in the blood smears or expression of CD103 or CD11c is seen in the neoplastic lymphocytes, HCL may come into the differential diagnosis. However, HCL typically shows interstitial or diffuse marrow infiltration and lacks prominent intrasinusoidal infiltration. The unique immunophenotype of HCL (i.e., increased side scatter, bright CD20 staining, and co-expression of CD103, CD11c, and CD25) usually easily discriminates HCL from SMZL. In questionable cases, demonstration of annexin-1, CD123, CD200, or cyclin D1 in the neoplastic cell by flow cytometric or immunohistochemical studies, or the presence of a *BRAF* V600E mutation, supports a diagnosis of

HCL.[73-75] However, distinction of SMZL from HCL variant based on bone marrow findings can be difficult and sometimes impossible, although the distinction is prognostically relevant.[76]

SMZL lacks a characteristic genetic abnormality although the majority of cases harbor genomic aberrations.[77] Deletion of chromosome 7q31-32, a common abnormality in myeloid neoplasm, has been identified in up to 40% of patients with SMZL and is rarely seen in other types of lymphoma. Recurrent mutations in SMZL include *NOTCH2* mutations in up to 25% and *KLF2* mutations in up to 40% of patients, and these mutations are uncommon in other B-cell lymphomas.[78,79] More recent data indicate two distinct genetic clusters in SMZL: the NNK group (harboring *NF-κB, NOTCH,* and *KLF* mutations) and the DMT groups (harboring mutations in genes related to DNA damage response, MAPK and TLR), and NNK group has inferior survival.[80]

Nodal Marginal Zone Lymphoma

Bone marrow involvement by NMZL has been reported in about 30% to 50% of cases. Focal random or interstitial infiltration is relatively common; paratrabecular infiltration occurs less frequently, and diffuse infiltration is rare.[81-83] The neoplastic infiltrates include small centrocyte-like cells with irregular nuclei, condensed chromatin, and scant cytoplasm; plasma cells or plasmacytoid cells may be intermixed in variable numbers. NMZL only occasionally involves the peripheral blood; the cytology of the circulating lymphoma cells is similar to that observed in bone marrow specimens.

Extranodal Marginal Zone Lymphoma of Mucosa-Associated Lymphoid Tissue

MALT lymphoma typically involves the gastrointestinal tract and is usually localized at diagnosis. Salivary gland, lung, thyroid, and conjunctiva are other commonly involved sites. When dissemination occurs, MALT lymphoma preferentially spreads to other mucosal sites. The incidence of bone marrow involvement varies in the reports, ranging from 5% to 44%.[84,85] Most bone marrow infiltrates are focal random, although paratrabecular, interstitial, or intrasinusoidal infiltration may also occur. The extent of bone marrow involvement is variable but usually low. The infiltrates of MALT lymphoma in the bone marrow include a spectrum of cells, ranging from small lymphocytes with condensed chromatin to slightly larger lymphocytes with irregular nuclei and ample cytoplasm; admixed plasma cells may also be present. Overt peripheral blood involvement by MALT lymphoma is uncommon.

Follicular Lymphoma

Low-grade (grades 1–2) FL involves the bone marrow at a higher frequency (50%–70%) than high-grade (grade 3) FL (15%–25%).[86,87] Distinct paratrabecular infiltration is the morphologic characteristic of FL in the bone marrow (**Fig. 55-16**), and can be identified, at least focally, in greater than 90% of cases; exclusively, paratrabecular infiltration also occurs.[9,17] Focal random infiltration is the most common pattern accompanying the paratrabecular lesions; diffuse and interstitial infiltration are less frequent and occur in 5% to 10% of cases.[9,14] A follicular growth pattern in the bone marrow is uncommon, accounting for less than 5% of cases

(**Fig. 55-17**). Similar to a lymph node, the follicular dendritic cell meshwork within the follicles can be highlighted by immunohistochemical staining for CD21 or CD23, and the neoplastic nature of the follicles can often be confirmed by positive staining for BCL2.[88] The bone marrow infiltrates are most frequently composed of small lymphocytes with condensed chromatin patterns and irregularly shaped nuclei (centrocytes). Large lymphocytes with prominent nucleoli (centroblasts) may be present, but usually are fewer in number. The lymphoma cells in the bone marrow aspirate smears are typically small-to-medium-sized with a deep nuclear cleft; similar cells are occasionally identified in the peripheral blood smear but are usually few in number. In a minority of cases, FL presents with an absolute lymphocytosis, and rarely, the lymphocytosis is marked (**Fig. 55-18**).[89] Rare FL may undergo blastoid transformation and morphologically mimic acute lymphoblastic leukemia.[90-92] In these cases, flow cytometric analysis is important to make the distinction.

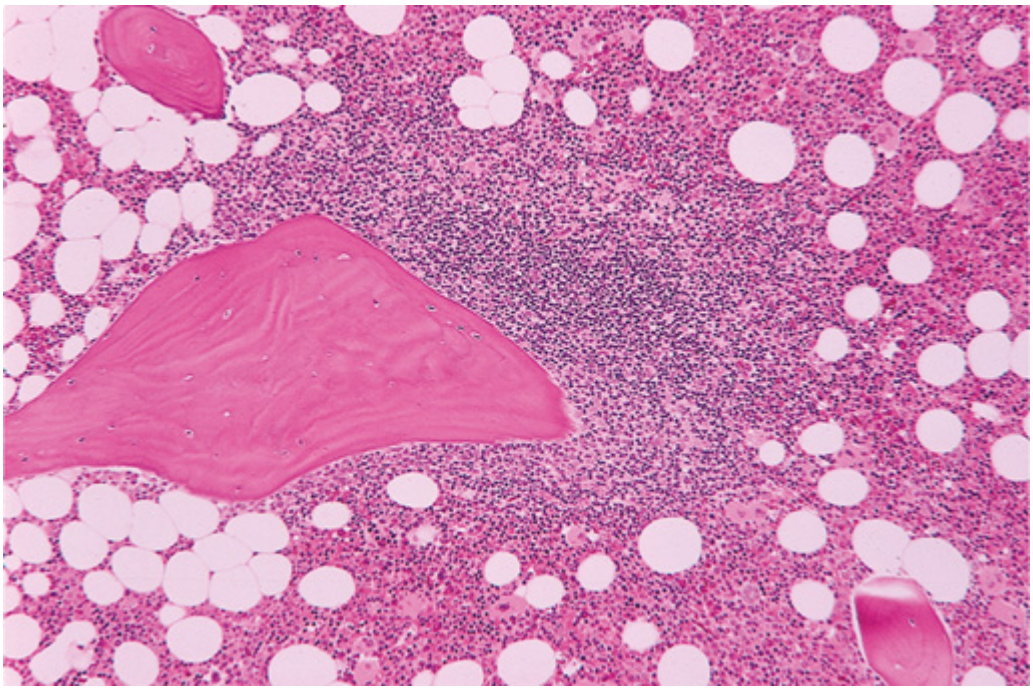

FIGURE 55-16 Follicular lymphoma with paratrabecular infiltration.The paratrabecular lymphoid infiltrates “hug” the bone and conform to its contour.

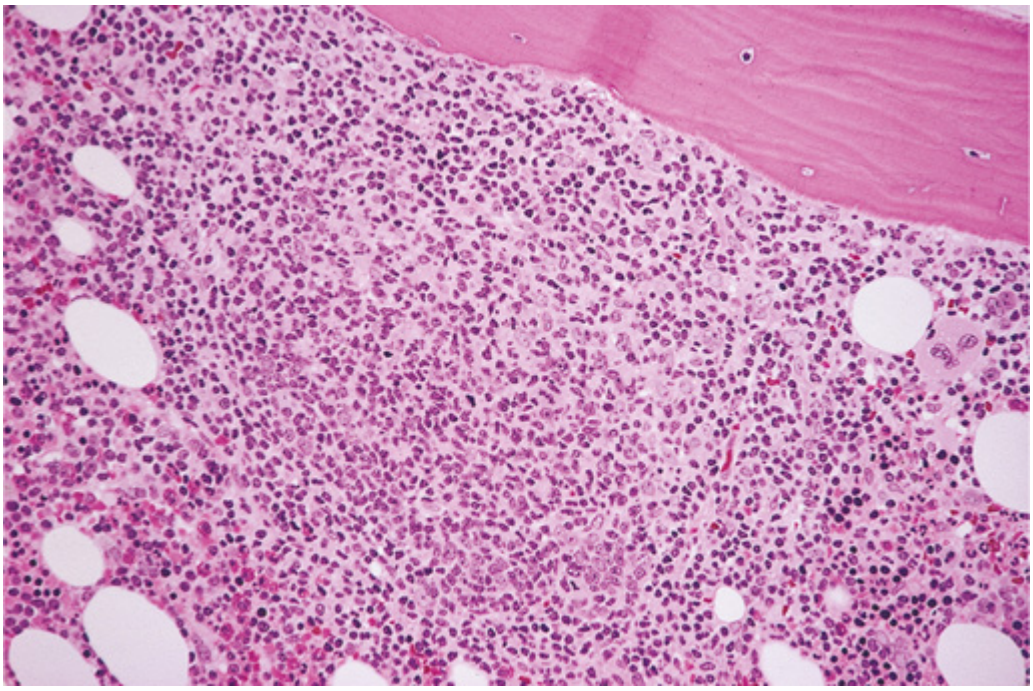

FIGURE 55-17 Follicular lymphoma with a follicular growth pattern.In this bone marrow core biopsy, the infiltrate is paratrabecular and contains a neoplastic follicle.

The classical immunophenotype of FL includes $CD19^+$, $CD20^+$, $CD5^-$, $CD10^+$, $BCL6^+$, and $BCL2^+$ with surface immunoglobulin light chain restriction. In the right morphologic context, identification of a CD10-positive monotypic B-cell population by flow cytometry, demonstration of CD10, or BCL6 expression support a diagnosis of FL. BCL2 is often positive in low-grade FL, but it should be interpreted in an architectural context because other types of small B-cell lymphomas frequently express BCL2.[93] It is noted that the frequency of CD10 positivity in the FL is lower in the bone marrow (~50%–60%) and peripheral blood (~40%) than in the primary site (~85%–95%) by both immunohistochemical and flow cytometric analysis.[93,94] Thus, CD10 negativity does not exclude FL, and a

panel of immunohistochemical stains may be required for an accurate subclassification of lymphoma in the bone marrow. Additionally, flow cytometry may fail to identify a monotypic B-cell population when FL is exclusively paratrabecular, likely because of the difficulty in aspirating these cells in the paratrabecular location.

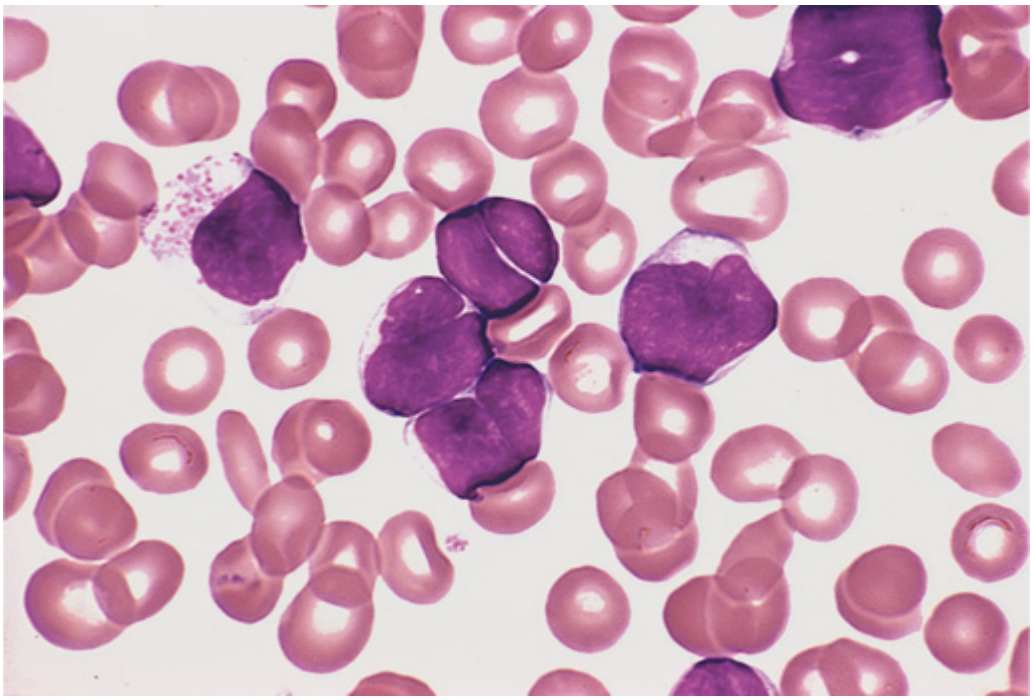

FIGURE 55-18 Follicular lymphoma cells in peripheral blood.The lymphoma cells are slightly larger than normal lymphocytes, and have slightly dispersed chromatin and deeply cleaved nuclei.

Distinguishing FL from other small B-cell lymphomas does not generally pose a diagnostic challenge because the majority cases demonstrate at least focal distinct paratrabecular infiltration. However, it is worth noting that paratrabecular infiltrate is not

diagnostic for FL; for example, MCL may occasionally show prominent or rarely exclusive paratrabecular infiltration (see discussion in "Mantle Cell Lymphoma"). Caution should also be taken in the evaluation of post-therapy bone marrow from patients with FL because in some effectively treated patients the paratrabecular lymphoid aggregates are composed entirely of T cells that architecturally mimic residual FL (**Fig. 55-6**). Additionally, discordant histologic subtypes of lymphoma between the bone marrow and the extramedullary site occurs. In the majority of the cases, the bone marrow is involved by a low-grade FL, whereas the extramedullary site has a higher-grade FL or DLBCL (**Fig. 55-19**). It has been reported that patients with nodal DLBCL and discordant, low-grade FL in the bone marrow have more favorable prognosis than patients with concurrent large B-cell involving the marrow.[9,14,95] Additionally, discordant morphology may also occur between bilateral bone marrow core biopsies in rare cases (**Fig. 55-20**).

Mantle Cell Lymphoma

MCL involves the bone marrow in 60% to 90% of cases.[43,82,96-98] The most common pattern of marrow involvement is focal random and is seen in over 80% of cases; interstitial and diffuse infiltration are present in about 50% and 20% to 30% of cases, respectively.[43,99] Notably, paratrabecular infiltration occurs in up to 45% of patients; occasionally, the infiltrate may be exclusively paratrabecular, resembling FL (**Fig. 55-21**).[43,99] Rare cases with prominent intrasinusoidal infiltration have also been reported.[100] The lymphoma cells can exhibit a heterogeneous morphology, but in

most cases, there is a uniform population of small-to-medium-sized lymphocytes with condensed chromatin and irregularly shaped nuclei. Occasionally the lymphoma cells are predominantly small with round nuclei and clumped chromatin, resembling CLL/SLL. The blastoid variant of MCL may mimic acute lymphoblastic leukemia in the peripheral blood and bone marrow (**Fig. 55-22**), and the pleomorphic variant of MCL resembles large B-cell lymphoma.[101,102] These variant MCLs tend to show interstitial or diffuse infiltration in the bone marrow.[101]

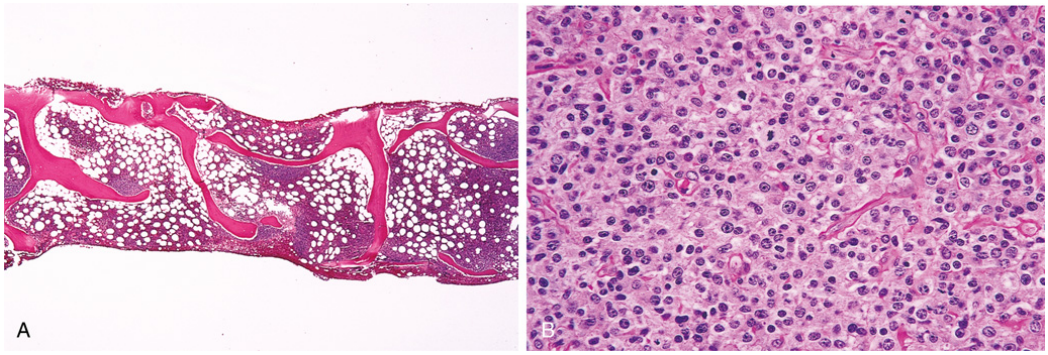

FIGURE 55-19 Diffuse large B-cell lymphoma with discordant morphology between lymph node and bone marrow.**A,** The bone marrow core biopsy contains several paratrabecular lymphoid aggregates composed of small lymphocytes. **B,** The lymph node biopsy shows diffuse large B-cell lymphoma.

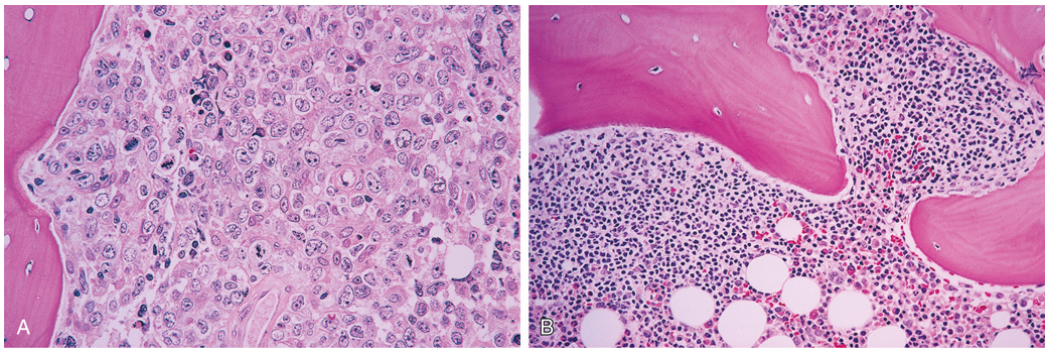

FIGURE 55-20 Lymphoma with discordant morphology in bilateral bone marrow core biopsies.**A,** Large B-cell lymphoma in the *right-sided* bone marrow core biopsy. **B,** Low-grade follicular lymphoma in the *left-sided* core biopsy. This patient has follicular lymphoma and diffuse large B-cell lymphoma in a lymph node biopsy.

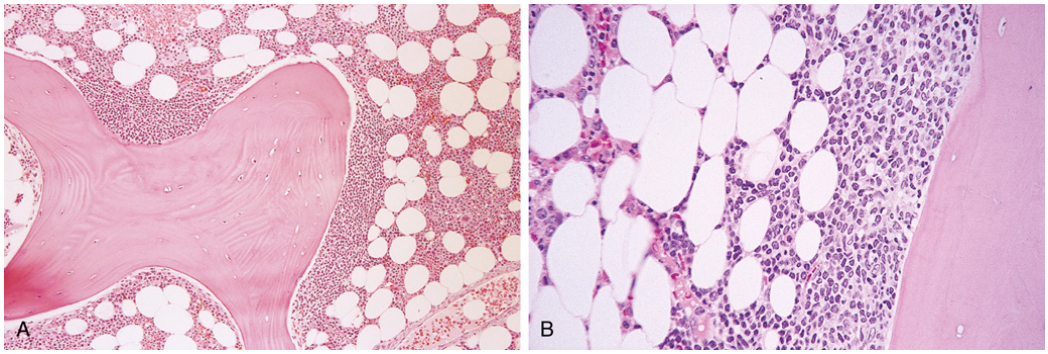

FIGURE 55-21 Mantle cell lymphoma with paratrabecular infiltration.**A,** The lymphomatous infiltrates are exclusively paratrabecular in this case. **B,** The lymphoma cells are small-to-medium-sized with condensed chromatin and round to irregular nuclei.

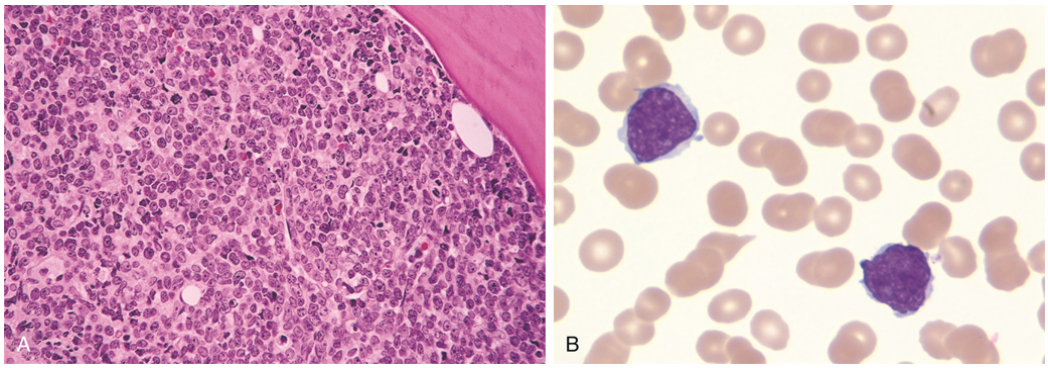

FIGURE 55-22 Mantle cell lymphoma, blastoid variant, in the bone marrow and peripheral blood.**A,** The infiltrate in the bone marrow core biopsy displays a diffuse infiltrative pattern and contains medium-to-large-sized cells with dispersed chromatin and one or more visible nucleoli. **B,** A blastoid lymphoma cell with cleaved nucleus, slightly dispersed chromatin, and scant cytoplasm is present in the peripheral blood.

Circulating lymphoma cells are common in MCL, and can be identified by morphologic evaluation of the peripheral blood smears in about 35% to 80% of patients.[43,82,97,99] An absolute lymphocytosis is present in up to 28% of patients.[43,96] MCL cells show a spectrum of cytologic appearance in the blood smear, and can be confused with other types of lymphoma. They may be small with round nuclei, resembling CLL/SLL; small-to-medium-sized with cleaved nuclei, mimicking FL; or medium-to-large-sized with a central prominent nucleolus, resembling prolymphocytic leukemia (**Fig. 55-23**). A clinically indolent variant of MCL has been recognized, primarily characterized by a leukemic presentation with

no or minimal nodal involvement and demonstrating morphologic features similar to CLL/SLL. In contrast to classical MCL, the indolent MCL is often positive for cyclin D1 but negative for SOX11 and harbors a mutated IGVH gene, indicating a post–germinal center origin.[103-105]

MCL and CLL/SLL are the two major CD5-positive small B-cell lymphomas that may display overlapping morphologic and immunophenotypic features. The presence of proliferation centers essentially rules out MCL, while distinct paratrabecular infiltration can occur in MCL but is absent in CLL/SLL. MCL is immunophenotypically characterized by bright CD20 and surface immunoglobulin light chain staining and is commonly $CD23^-$, $CD79b^+$, $FMC7^+$, and $CD200^-$, whereas CLL/SLL typically demonstrates dim CD20 and surface immunoglobulin light chain staining and is $CD23^+$, $CD79b^-$, $FMC7^-$, and $CD200^+$. However, variations in phenotype occur in MCL, including negative staining for CD5 and overlapping immunophenotype with CLL in the expression of CD23 and FMC7; rarely, MCL may express CD10.[106] Therefore, a diagnosis of MCL should not be solely based on the flow cytometric results.[107,108]

Overexpression of cyclin D1 (BCL1) serves as a convenient immunohistochemical marker for diagnosis of MCL. When immunohistochemical staining is equivocal, fluorescence in situ hybridization (FISH) analysis for t(11;14)-*CCND1*/*IGH* may be required for confirmation (**Fig. 55-24**). It is worth mentioning that cyclin D1 is not exclusively overexpressed by MCL, as a majority of HCL and a subset of plasma cell myeloma are also positive for cyclin D1. Fortunately, these two diseases rarely enter into the differential

diagnosis of MCL because of their distinct clinicopathologic features. SOX11 has been shown to be highly specific for MCL, and serves as an additional marker for MCL (**Fig. 55-8**).[109,110] It is particularly useful in the diagnosis of cyclin D1-negative MCL.[111,112] However, the indolent variant of MCL may lack overexpression of SOX11.[105,113] When used in combination, immunohistochemical stains for cyclin D1, SOX11, and LEF1 (discussed earlier in CLL/SLL) provide highly effective adjunct in diagnosis and differential diagnosis of small B-cell lymphomas.

Diffuse Large B-Cell Lymphoma

DLBCL is a heterogeneous group of tumors in terms of clinical, morphologic, and genetic features.[114] DLBCL, in general, infiltrates the bone marrow in about 10% to 30% of cases.[42,115-117] However, cases with both *MYC* and *BCL2* or *BCL6* gene rearrangement have a higher incidence of bone marrow involvement, ranging from 42% to 93%.[118-121] Focal random, diffuse, and mixed patterns of infiltration are common; paratrabecular infiltration occurs occasionally; and interstitial infiltration is uncommon.[9,17,122] The neoplastic cells may demonstrate a wide range of morphology but are typically large with one or more prominent nucleoli. DLBCL infiltrate is usually easily identified on H&E-stained bone marrow sections (**Fig. 55-25**). The aspirates or touch imprints occasionally contain lymphoma cells (**Fig. 55-25**). Peripheral blood involvement is uncommon but does occur.

As mentioned earlier, in approximately 20% to 45% of patients with DLBCL, the bone marrow and extramedullary site show discordant histology subtype, often characterized by a low-grade

lymphoma, most commonly FL, in the bone marrow and DLBCL in the extramedullary site (**Fig. 55-19**).[9,42,116,117,122] Molecular analysis of IGH or *BCL2* gene rearrangements in 16 discordant cases revealed that in two-thirds of the patients, the low-grade lymphoma in the marrow was clonally related to the DLBCL in the primary site, while in the remaining one-third of the patients, the two lymphoma subtypes were clonally unrelated.[123] It has been reported that patients with DLBCL who have a discordant, low-grade lymphoma in the bone marrow have an overall treatment response and survival similar to those without marrow involvement, but patients with concordant DLBCL in the bone marrow have a lower overall survival, and lower progression-free and disease-free survivals.[116,117,124-127]

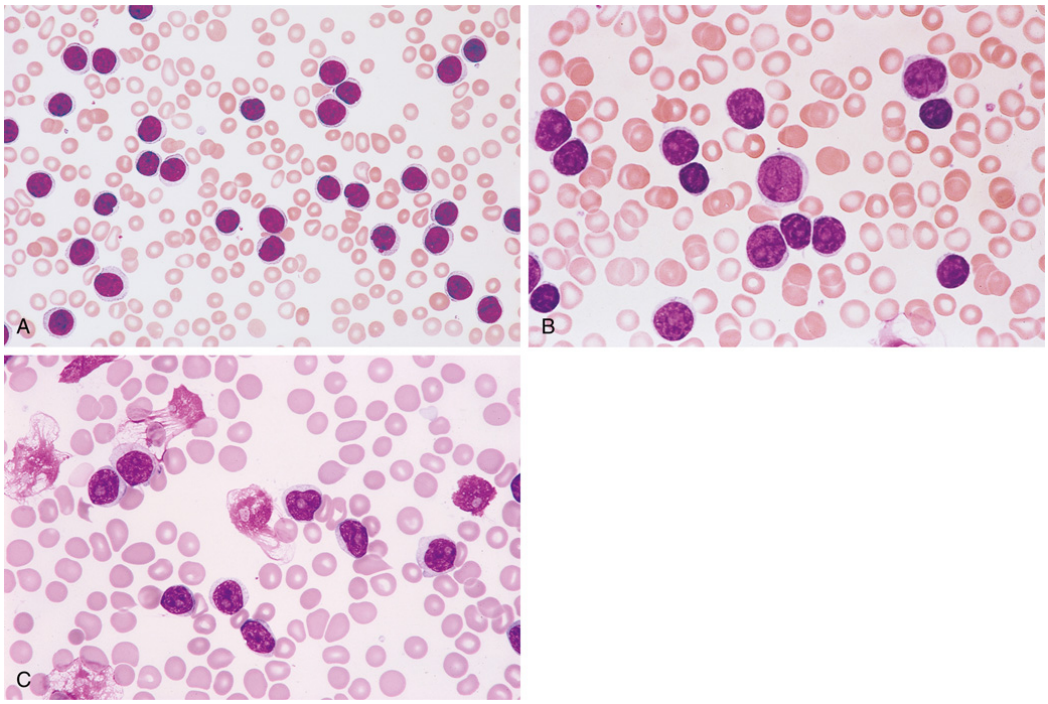

FIGURE 55-23 Leukemic phase of mantle cell lymphoma mimicking chronic lymphocytic leukemia (CLL) or prolymphocytic leukemia (PLL).**A,** The blood smear shows an absolute lymphocytosis (66×10^9/L). The lymphoma cells are small with round or slightly irregular nuclei, condensed chromatin and scant cytoplasm that closely resemble CLL cells. **B,** This case shows an absolute lymphocytosis (134×10^9/L) composed of variably sized lymphoma cells. Some cells are small with condensed chromatin, and others are medium-sized with slightly dispersed chromatin and prominent, central nucleolus, resembling CLL/PLL. **C,** The lymphoma cells in this case are medium-to-large-sized with ample cytoplasm,

condensed chromatin, and a prominent central nucleolus, resembling PLL.

Immunophenotypically, DLBCL is highly heterogeneous; however, a diagnosis of DLBCL can generally be made based on the morphologic findings and documentation of B-cell lineage of the large cells, such as expression of CD20, CD79a, or PAX5. When CD5 is expressed, immunohistochemical staining for cyclin D1 or SOX11 should be performed to exclude the possibility of a variant MCL. Rarely, CD20 can be aberrantly expressed in peripheral T-cell lymphoma or CD3 in DLBCL[128,129]; therefore, using additional B-cell and T-cell markers is necessary in these cases to accurately determine the lineage of the lymphoma; in some cases, molecular analysis for B-cell or T-cell clonality may be required.

There are a number of clinicopathologically distinct large B-cell lymphomas, such as T cell/histiocyte-rich large B-cell lymphoma (THRLBCL), EBV-positive large B-cell lymphoma, and primary mediastinal large B-cell lymphoma (PMLBCL).[65,66] THRLBCL exhibits abundant reactive T cells and histiocytes but only scattered large neoplastic B cells.[130] When involving the bone marrow, THRLBCL may be difficult to distinguish from reactive infiltrates or other lymphomas that often have heterogeneous cellular compositions, such as HL or peripheral T-cell lymphoma (**Fig. 55-26**). Multiple levels of bone marrow sections may be necessary to confirm the presence of abnormal large lymphocytes within the infiltrates, and a panel of immunohistochemical stains is often required for diagnosis. The scattered large, abnormal cells in THRBCL are positive for CD45 and CD20, but negative for CD30, CD15, and CD3, which helps exclude classic Hodgkin lymphoma

(CHL) and peripheral T-cell lymphoma. EBV-encoded RNA (EBER) staining is necessary to exclude EBV-positive large B-cell lymphoma. In most cases, however, an extramedullary tissue biopsy is indicated except for cases of isolated splenic micronodular THRLBCL that frequently show isolated marrow involvement without adenopathy.[131] PMLBCL is a subtype of large B-cell lymphoma that arises in the mediastinum and has a female predominance.[132] Bone marrow involvement by PMLBCL has been reported in 2% to 9% of cases, but the characteristics of marrow infiltration have not been described in detail, although extramediastinal involvement has been documented.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma (IVLBCL) is an uncommon variant of extranodal large B-cell lymphoma that is localized within the small blood vessels, particularly capillaries. It is usually widely disseminated in extranodal sites, including bone marrow.[133-136] Because of the non-specific clinical features, bone marrow may be the initial diagnostic site for IVLBCL.[133,136] In a retrospective study of bone marrow biopsies performed for evaluation of fever of unknown origin or hemophagocytic syndrome, 12 of 146 (8.2%) patients were found to have IVLBCL in the bone marrow.[133] Morphologically, the neoplastic infiltrates in the marrow are predominantly confined to the sinusoids (**Fig. 55-27**); they may cause apparent distention of the sinusoids or may be subtle and difficult to appreciate on H&E-stained section. However, immunohistochemical staining for B-cell markers, such as CD20, CD79a, or PAX5, can highlight the lymphoma cells and delineate the

intrasinusoidal pattern of infiltration (**Fig. 55-27**). IVLBCL exhibits heterogeneous immunophenotype similar to other LBCLs; however, CD5 expression is reportedly more frequent than LBCLs in general.[133,136]

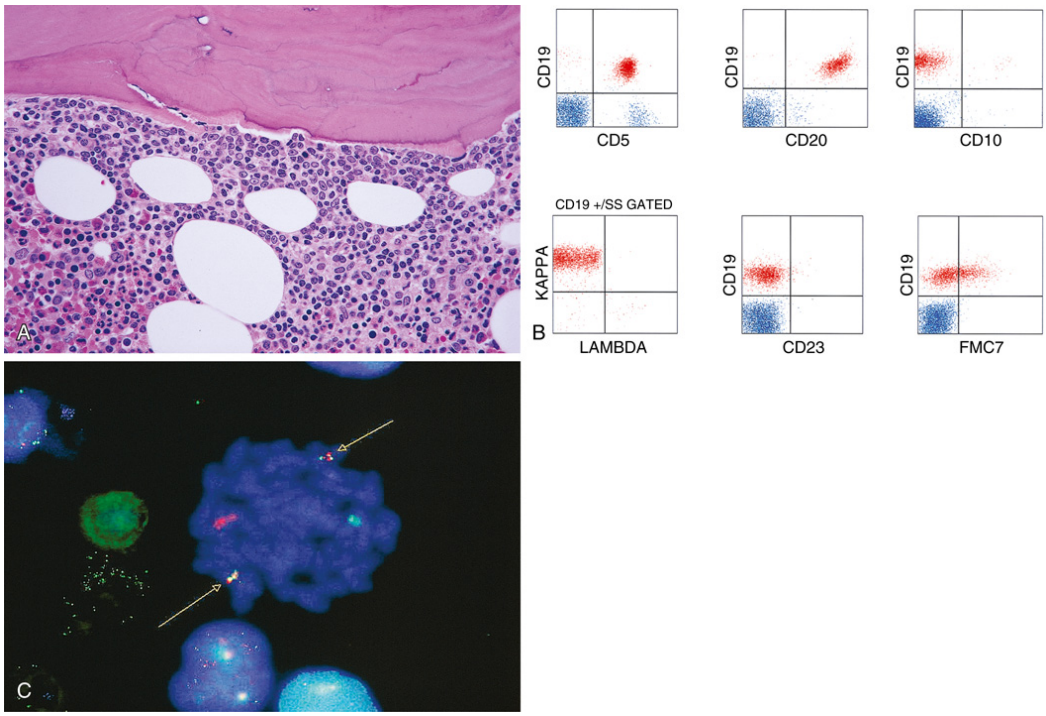

FIGURE 55-24 Mantle cell lymphoma diagnosed initially on a bone marrow biopsy.**A,** The infiltrate is paratrabecular and consists of small-to-medium-sized lymphocytes with irregular nuclei. **B,** The histograms of flow cytometric immunophenotyping of the bone marrow aspirate demonstrates a surface kappa-restricted B-cell population that is $CD19^{+}$, $CD20^{+}$, $CD5^{+}$, $CD10^{-}$, $CD23^{-}$, and dim $FMC7^{+}$. CD200 is negative in mantle cell lymphoma (MCL) (not shown). **C,** Fluorescence in situ hybridization using probes to the immunoglobulin heavy chain gene (IGH; *green*) and *CCND1* gene *(orange)* demonstrates a yellow fusion signal *(arrows)*, indicating t(11;14)-*CCND1*::*IGH* fusion. A subsequent lymph node biopsy confirmed the

diagnosis of MCL. *(C, Courtesy of Dr. Gordon Dewald, Mayo Medical Laboratories, Rochester, MN.)*

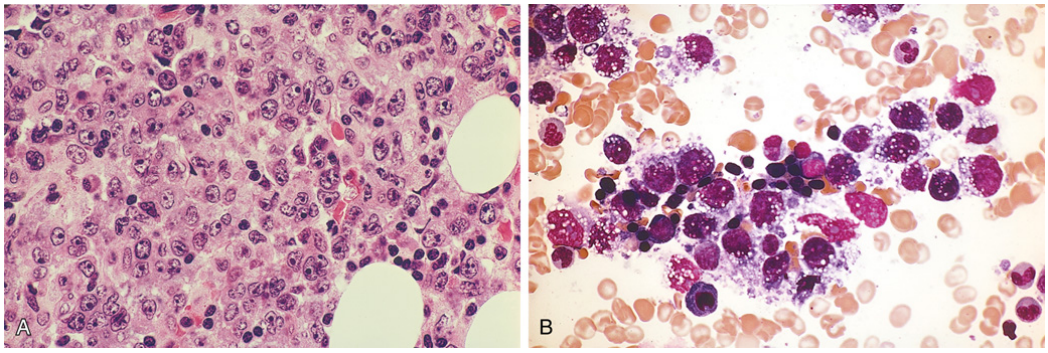

FIGURE 55-25 Diffuse large B-cell lymphoma in a bone marrow core biopsy and aspirate smear.**A,** Lymphoma cells in the bone marrow core biopsy are large with irregular nuclei, vesicular chromatin and distinct nucleoli. **B,** The lymphoma cells in the bone marrow aspirate contain cytoplasmic vacuoles in this case.

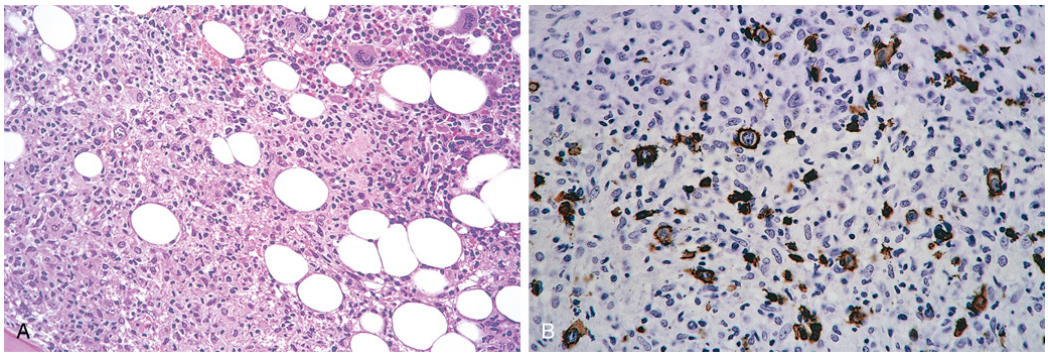

FIGURE 55-26 T-cell/histiocyte-rich large B-cell lymphoma involving the bone marrow.**A,** The infiltrate has poorly defined borders and contains many small lymphocytes, histiocytes, and scattered large, abnormal lymphocytes. **B,** Immunohistochemical staining for CD20 highlights the scattered large lymphoma cells. The majority of the cells are CD3-positive T cells (not shown). A micronodular pattern of involvement resembling nonnecrotizing granulomas may be seen in this lymphoma.

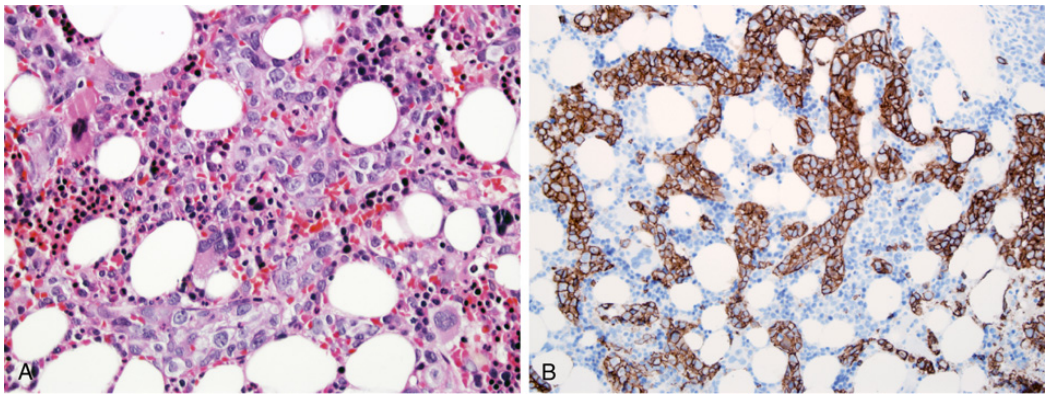

FIGURE 55-27 Intravascular large B-cell lymphoma in a bone marrow core biopsy.**A,** The lymphoma cells are present within the sinusoid, and can be missed in hematoxylin and eosin (H&E)-stained sections. **B,** Immunohistochemical staining for CD20 highlights the lymphoma cell in the sinusoids.

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL) is a large B-cell lymphoma that most commonly occurs in HIV-infected patients, primarily involves body cavities, and presents as a lymphomatous effusion. Solid PEL occurring in extracavitary sites have also been reported.[137-139] PEL is universally associated with human herpesvirus 8 (HHV-8); EBV coinfection is common. Cytologically, the tumor cells may show plasmablastic, immunoblastic, or anaplastic appearance. Immunohistochemical staining to demonstrate HHV8 infection using antibody against HHV8-encoded latency-associated nuclear antigen (LANA) serves as a key diagnostic feature for PEL. PEL displays a phenotype of terminally differentiated B cells: positive for CD45, negative for pan B-cell markers, negative for surface

immunoglobulin, and positive for activation and plasma-cell associated markers (CD138, CD38, MUM-1, CD30, and EMA).[139,140] The data on bone marrow involvement by PEL are limited. In a study of 12 cases of PEL, bone marrow involvement was found in one of nine cases in the form of large sheets of tumor cells.[140]

Burkitt Lymphoma

BL involves the bone marrow in about 30% to 60% of cases, most often with a diffuse or interstitial pattern of infiltration.[14,141] The starry-sky pattern typically seen at extramedullary sites can also be present in the bone marrow biopsy; necrosis is common and can be extensive. Concurrent blood involvement is common, ranging from occasional lymphoma cells to overt lymphocytosis; however, a pure leukemic presentation is rare. Cytologically, BL cells are monotonous appearing, medium-sized, with reticular chromatin, multiple small nucleoli, deeply basophilic cytoplasm, and frequent mitoses. Abundant cytoplasmic vacuoles are common, and best appreciated in the bone marrow aspirate smears (**Fig. 55-28**), touch preparation, or peripheral blood smears. It has been reported that primary leukemic and marrow involvement ("Burkitt leukemia") at diagnosis has a better outcome compared with secondary marrow involvement by BL.[142]

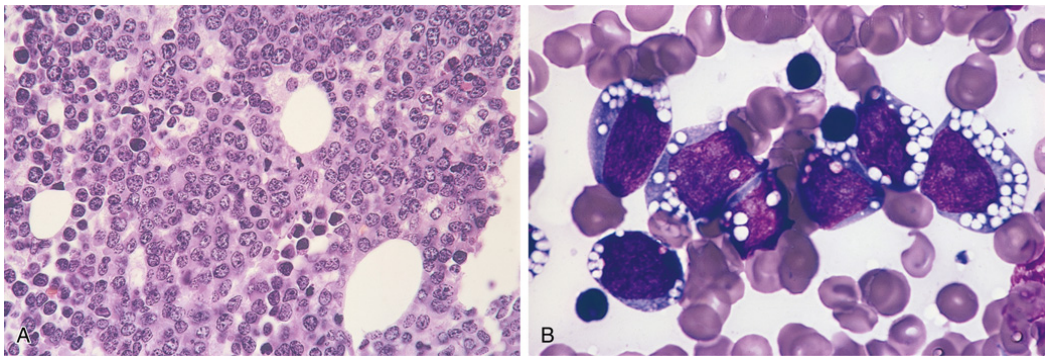

FIGURE 55-28 Burkitt lymphoma in the bone marrow core biopsy and aspirate smear.**A,** The bone marrow core biopsy contains a diffuse infiltration of monotonous, medium-sized lymphocytes with several small nucleoli, and scant to moderate amounts of cytoplasm. Frequent mitoses are present. **B,** The bone marrow aspirate contains lymphoma cells with basophilic cytoplasm and multiple cytoplasmic vacuoles.

BL is typically $CD19^+$, $CD20^+$, $CD10^+$, and $BCL6^+$; BCL2 is typically negative but may be weakly positive in occasional cases. BL has an extremely high proliferation rate with Ki67 positivity in virtually 100% of tumor cells. The genetic hallmark of BL is *MYC* gene rearrangement, which can be detected by FISH or conventional karyotyping.

BL should be differentiated from other aggressive B-cell neoplasms, such as B-lymphoblastic leukemia/lymphoma, blastoid MCL, and high-grade large B-cell lymphoma. In general, BL can be easily distinguished from B-lymphoblastic leukemia/lymphoma by flow cytometry immunophenotyping. B-lymphoblastic

leukemia/lymphoma expresses one or more of the immature markers CD34 and TdT, and lacks surface immunoglobulin expression; additionally, *MYC* gene rearrangement is rare (~1%).[143] Blastoid MCL can be excluded by negative immunohistochemical staining for cyclin D1 and SOX11. P53 is often overexpressed in blastoid MCL. The distinction of BL from high-grade B-cell lymphoma is discussed later.

High-Grade B-Cell Lymphoma

High-grade B-cell lymphoma (HGBL) includes three subtypes based on the ICC classifications: HGBL with *MYC* and *BCL2* rearrangements (double-hit lymphoma [DHL]-*BCL2*); HGBL with *MYC* and *BCL6* rearrangements (DHL-*BCL6*; provisional entity); and HGBL, NOS.[65,66] DHL-*BCL2* is an aggressive B-cell lymphoma of germinal center origin with distinct biology from HGBL-*MYC*/*BCL6* and DLBCL-GCB, while DHL-*BCL6* is frequently of non-GCB origin with heterogenous molecular alterations and clinical behaviors. Some studies have demonstrated that *MYC/BCL6* rearrangements do not predict poorer survival in DLBCL patients.[144-146] HGBL, NOS, is an aggressive B-cell lymphomas that often shows blastoid or Burkitt-like morphology without double-hit or triple-hit molecular alterations. HGBL involves the bone marrow at a higher frequency (42%–93%) than DLBCL in general (10%–25%).[118,119,121]

The distinction of HGBL types from BL can be challenging even in the lymph node biopsy because they can exhibit overlapping cytomorphology. Features favoring HGBL over BL include variations in cell or nuclear size, irregular nuclear contours, prominent nuclei,

rearranged *BCL2* or *BCL6* gene, or complex karyotype. Additionally, expression of BCL2 or MUM1, Ki67 less than 95%, and absence of EBV also favor HGBL.[121,147]

B-Lymphoblastic Leukemia/Lymphoma

B-lymphoblastic leukemia/lymphoma is a neoplasm of precursor B cells. It commonly involves blood and bone marrow (B-acute lymphoblastic leukemia [B-ALL]), or occasionally primarily involves nodal or extranodal sites (B-lymphoblastic lymphoma [B-LBL]).[148] B-ALL often shows extensive, diffuse bone marrow infiltration, sometimes entirely replacing the marrow. B-LBL is defined arbitrarily as lymphomatous presentation with less than 25% bone marrow involvement.[149] In a study of 25 cases of B-LBL without concurrent B-ALL, the most common primary sites include skin, bone, soft tissue, and lymph node.[150] With aggressive chemotherapy, patients with B-LBL rarely develop leukemia and appear to have a better prognosis than patients with B-ALL.[150]

When bone marrow is involved, B-LBL infiltrate is usually focal random. The blasts are often uniformly small-to-medium-sized, with fine chromatin; scant, occasionally vacuolated cytoplasm; indistinct nucleoli; and frequent mitoses. B-LBL can be difficult to distinguish from some mature B-cell lymphomas, such as BL or blastoid MCL. Immunophenotypic analysis is crucial in making this distinction. Demonstration of TdT or CD34 expression in the neoplastic cells can essentially exclude a mature B-cell lymphoma. The subclassification of B-ALL/LBL is now largely based on the defining cytogenetic and molecular abnormalities that are discussed in detail in Chapter 41.

T-Cell Lymphomas Involving Bone Marrow

This section describes the characteristics of selected subtypes of T-cell lymphomas with emphasis on the morphologic features specific to the bone marrow involvement. Other features such as immunophenotype and molecular cytogenetic features are briefly discussed, and more details can be found in the specific chapters of these entities.

T-Lymphoblastic Leukemia/Lymphoma

Overall, T-lymphoblastic leukemia/lymphoma (T-ALL/LBL) more commonly has a lymphomatous presentation compared with B-ALL/LBL. Similar to its B-cell counterpart, the designation of T-LBL is used when bone marrow involvement is absent or less than 25%. When bone marrow is involved, the core biopsy shows focal random infiltrates of blasts with scant cytoplasm (**Fig. 55-29**). Blasts range from small to large cells with dispersed or condensed chromatin and may have convoluted nuclei. T-LBL is positive for cytoplasmic CD3, CD7, and expresses one or more of immature markers (CD34, TdT, CD1a, and CD99) and variably expresses CD4 or CD8, depending on the stage of maturation. It is worth noting that hematogones can also express TdT; therefore, it is important not to construe minimal T-ALL or B-ALL solely based on the TdT immunohistochemical staining (**Fig. 55-29**).[151]

Extranodal Natural Killer/T-Cell Lymphoma

Extranodal NK/T-cell lymphoma (ENKTL) frequently arises in the nasal cavity (80%), termed *ENKTL, nasal type*. It may also occur

outside the nasal cavity (20%), commonly in the skin, gastrointestinal tract, and testis.[152,153] The cytology of the tumor cells varies from small, medium, to large-sized cells or a mixture of variably sized tumor cells. The incidence of bone marrow involvement by ENKTL has been reported from 8% to 23%.[46,47,50,154-157] Typically, singly distributed lymphoma cells are found in the interstitial areas of the bone marrow, and can be difficult to identify on H&E-stained sections. In contrast to nasal NKTCL that is localized to the upper aerodigestive tract at presentation, most patients with nonnasal type present with advanced disease involving multiple anatomic sites, including bone marrow involvement in 15% to 25% of cases.[50,153,158,159]

The ENKTL usually exhibits an NK cell phenotype, (i.e., negative for surface CD3 by flow cytometric analysis of surface-antigen expression, but positive for cytoplasmic CD3ε that can be detected by flow cytometric analysis with cytoplasmic CD3 staining or immunohistochemistry. The lymphoma cells are also typically CD56 positive and EBV positive. In situ hybridization for EBER or immunohistochemical staining for CD56 can highlight the isolated tumor cells in the bone marrow (**Fig. 55-30**). Hemophagocytic syndrome has been described in patients with ENKTL.[158-160]

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) typically arises in the small intestine as a complication of long-standing celiac disease.[161] Bone marrow involvement is rare, and has been reported in 2% to 8% patients.[46,161,162] However, no details about the pattern of bone marrow involvement have been described.

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) is a rare, highly aggressive peripheral T-cell lymphoma, predominantly TCRγδ subtype, that occurs in adolescents, young adults, and older individuals over the age of 60 years (about 50% of cases) with male predominance.[65] Patients often present with marked splenomegaly without lymphadenopathy, anemia, and marked thrombocytopenia.[48,65] HSTCL involves the peripheral blood or bone marrow in almost all cases, and the marrow involvement is characterized by a prominent intrasinusoidal infiltration associated with a hypercellular bone marrow with trilineage hyperplasia.[163] The infiltrate can be difficult to appreciate on H&E-stained sections, but immunohistochemical staining for CD3 highlights the intrasinusoidal lymphoma cells that often cause distension of the sinusoids (**Fig. 55-31**).[164,165] The lymphoma cells vary from small-to-medium-sized with condensed chromatin to blastic or pleomorphic cells (**Fig. 55-31**). The blastic-appearing lymphoma cells and the interstitial infiltration increase with the disease progression.[165]

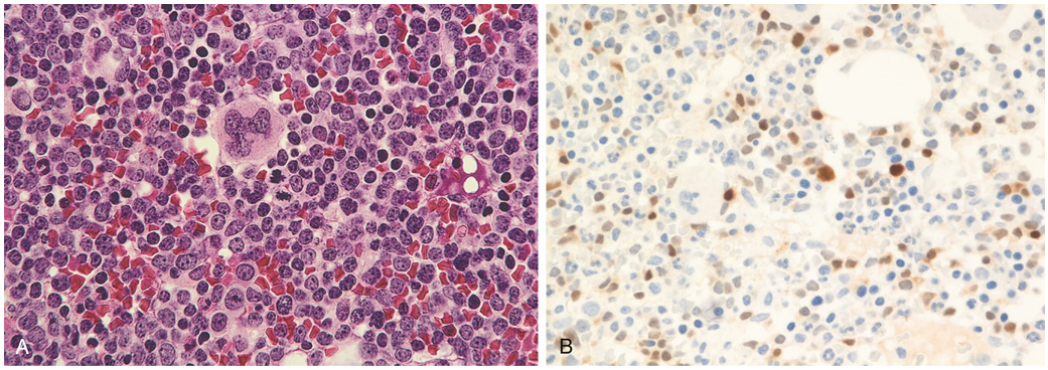

FIGURE 55-29 T-lymphoblastic leukemia/lymphoma involving the bone marrow.A, The bone marrow core biopsy demonstrates diffuse infiltration of neoplastic cells, replacing almost the entire bone marrow. The cells are small-to-medium-sized with slightly dispersed chromatin. A few mitotic figures are present. Flow cytometry immunophenotyping and immunohistochemical stains for CD3, TdT, CD1a, or CD99 are helpful for diagnosis (not shown). **B,** Image from a normal bone marrow showing occasional TdT-positive cells. It is important not to construe minimal T-lymphoblastic leukemia (T-ALL) solely based on the TdT immunohistochemical staining in the bone marrow as hematogones can also express TdT.

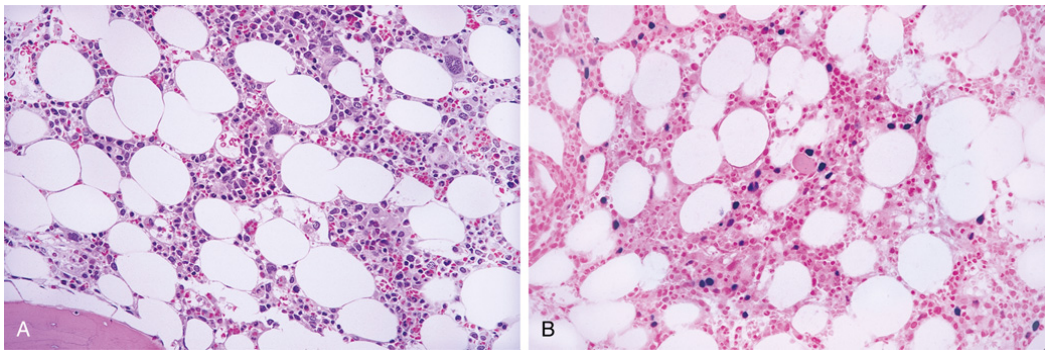

FIGURE 55-30 Natural killer/T-cell lymphoma, nasal type, involving the bone marrow.**A,** The tumor cells are difficult to appreciate on hematoxylin and eosin (H&E)–stained bone marrow core biopsy. **B,** In situ hybridization for Epstein-Barr virus–encoded RNA (EBER) highlights the scattered tumor cells.

Most cases of HSTCL arise from cytotoxic memory T cells, and the lymphoma cells are typically $CD3^+$, TCR $\gamma\delta^+$, $CD4^-$, $CD8^{-/+}$, $CD5^-$, $CD2^+$, $CD7^+$, $CD56^{+/-}$, $CD57^-$, and have a nonactivated cytotoxic T-cell phenotype (i.e., $TIA1^+$, granzyme M^+, granzyme B^-, and perforin).[48,164,165] A TCR αβ variant has been reported in a small number of cases and shows similar clinicopathologic features to γδ HSTCL.[166,167] EBV is consistently negative. Isochromosome 7q (i7q) is a recurrent genetic abnormality in HSTCL, often associated with trisomy 8.[149] The frequency of i7q varies in the reports. Approximately 70% of cases were positive in large series of studies, and the negative cases were mostly based on the conventional karyotyping rather than FISH.[48,168]

The differential diagnosis of HSTCL in the bone marrow is largely restricted to leukemia/lymphoma with propensity for sinusoidal

infiltration. The B-cell lymphomas, such as intravascular large B-cell lymphoma and SMZL, can be easily excluded by positive staining for B-cell markers. Among T-cell leukemia/lymphoma, T-cell large granular lymphocytic leukemia (T-LGLL) is also associated with splenomegaly and has a predilection for an intrasinusoidal distribution in the bone marrow.[169] In particular, a rare variant of $CD4^-/CD8^-$ γδ T-LGLL demonstrates an immunophenotype overlapping with HSTCL ($CD3^+$, $CD5^-$, $CD4^-$, $CD8^-$, TCR $γδ^+$, and $TIA1^+$), and may cause diagnostic confusion with HSTCL.[170-173] Clinically, γδ T-LGLL is an indolent disease primarily affecting older individuals, similar to the common type of CD8-positive T-LGLL.[170,174] The pattern of bone marrow infiltration by $CD4^-/CD8^-$ γδ T-LGLL is also similar to common T-LGLL (i.e., predominantly interstitial accompanied by a relatively small component of intrasinusoidal infiltration). The latter differs from HSTCL in that it rarely expands the sinusoids but takes the form of a short, linear array (often one-cell layer) of lymphocytes within the sinusoids (**Fig. 55-32**). The neoplastic cells in T-LGLL are morphologically indistinguishable from normal LGLs with no cytologic atypia. Additionally, i7q has not been reported in T-LGLL. It is important to include this rare variant of T-LGLL in the differential diagnosis because HSTCL is a highly aggressive lymphoma that requires chemotherapy, and bone marrow transplant may be considered; however, γδ T-LGLL is an indolent disease that may respond to immunomodulating agents, and bone marrow transplant is not indicated.

Other types of T or NK cell leukemia/lymphoma, such as aggressive NK cell leukemia, T-cell prolymphocytic leukemia (T-

PLL), and adult T-cell leukemia and lymphoma (ATLL) often involve blood and bone marrow. However, these leukemia/lymphomas rarely show prominent intrasinusoidal infiltration in the bone marrow. Additionally, immunophenotyping can often discriminate HSTCL from these T or NK cell leukemia/lymphomas (e.g., aggressive NK cell leukemia exhibits an NK-cell phenotype and is always EBV positive; T-PLL and ATLL are both TCR αβ positive and predominantly CD4 positive.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) is a rare neoplasm of cytotoxic (CD8 positive) T cells that has a predilection for subcutaneous tissue.[175,176] The diagnosis of SPTCL is now restricted to those expressing TCR αβ. SPTCL remains localized in the subcutaneous tissue and rarely involves the bone marrow.[177,178] A limited number of case reports described focal bone marrow involvement by SPTCL with morphologic features similar to the subcutaneous site (i.e., prominent rimming of the adipocytes by the neoplastic lymphocytes) (**Fig. 55-33**). These cells are small with condensed chromatin and scant cytoplasm, and are positive for CD3, CD8, βF1 and cytotoxic granule proteins (TIA1, granzyme B, and perforin). The recurrent germline mutations in *HAVCR2,* encoding T-cell immunoglobulin mucin 3, have been recently identified in 25% to 80% of patients with SPTCL and are associated with younger age and hemophagocytic lymphohistiocytosis (HLH) or HLH-like systemic illness.[179]

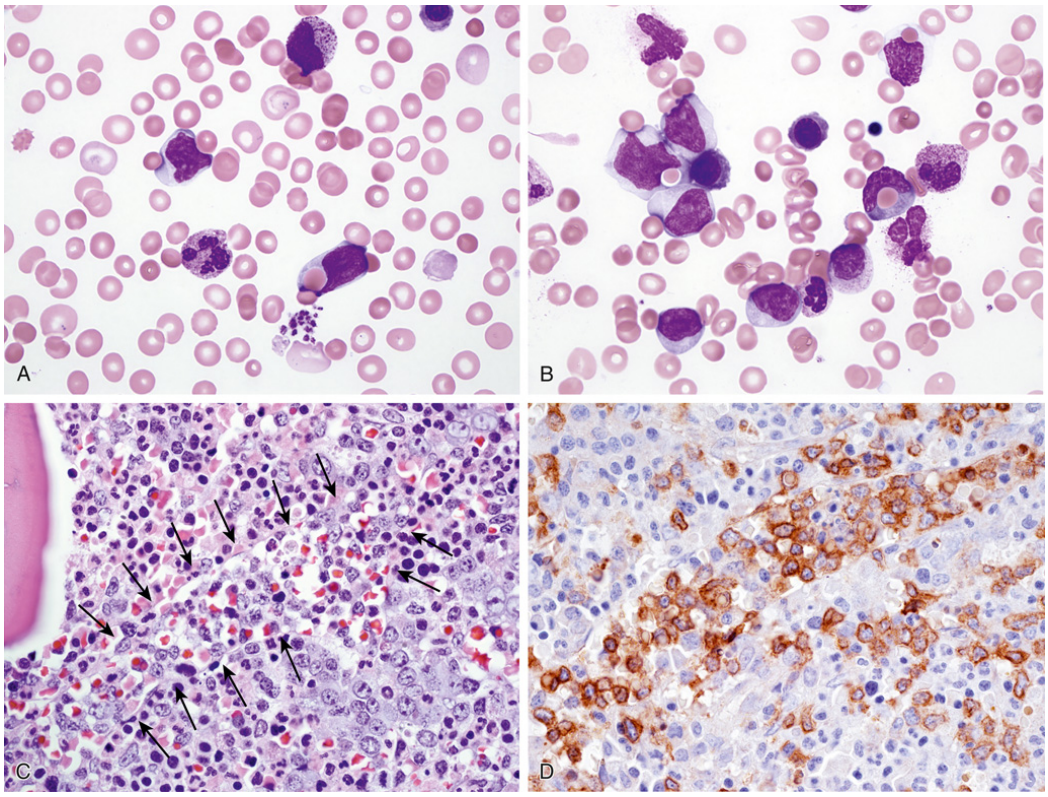

FIGURE 55-31 Hepatosplenic T-cell lymphoma involving peripheral blood and bone marrow.**A,** The lymphoma cells in the blood smears resemble blasts; some of the lymphoma cells show erythrophagocytosis. **B,** Lymphoma cells in the bone marrow aspirate smears show similar morphology to those in the peripheral blood smears. **C,** The bone marrow core biopsy shows intrasinusoidal infiltration of lymphoma cells that expand the sinusoids *(arrows)*. **D,** Immunohistochemical staining for CD3 highlights the lymphoma cells within the sinusoids. This patient had a classical clinical presentation and characteristic immunophenotype for hepatosplenic T-cell

lymphoma (HSTCL), and fluorescence in situ hybridization (FISH) was positive for isochromosome 7q.

Mycosis Fungoides and Sézary Syndrome

MF is the most common primary cutaneous T-cell lymphoma that generally remains localized for years, and Sézary syndrome (SS) is a rare disorder characterized by diffuse erythroderma, lymphadenopathy, and circulating lymphoma cells (Sézary cells).[180] The incidence of bone marrow involvement by MF or SS has been reported from less than 2% to 25% at initial diagnosis.[51,181,182] The extent of bone marrow infiltration is usually minimal to mild, and is focal random or interstitial, or both; paratrabecular and diffuse infiltrates are rare.[183] The infiltrates are composed primarily of variably sized abnormal lymphocytes with convoluted nuclei, and the infiltrates are often subtle and difficult to recognize on H&E-stained sections. Immunohistochemical stains for T-cell markers, such as CD3, aid in the recognition of lymphoma cells (**Fig. 55-34**). However, even with immunohistochemical stains, there is poor agreement between histologic-immunophenotypic detection of disease and molecular studies for T-cell clonality.[184]

The number of circulating lymphoma cells in SS is highly variable, ranging from occasional cells to a frankly leukemic picture. The neoplastic lymphocytes may be small or large with variable amounts of cytoplasm. The nuclei are characterized by striking convolutions that may give them a cerebriform appearance; nucleoli are absent or inconspicuous (**Fig. 55-34**). The lymphoma cells are typically $CD3^+$, $CD4^+$, $CD8^-$, $CD7^-$, and $CD26^-$ (**Fig. 55-35**).

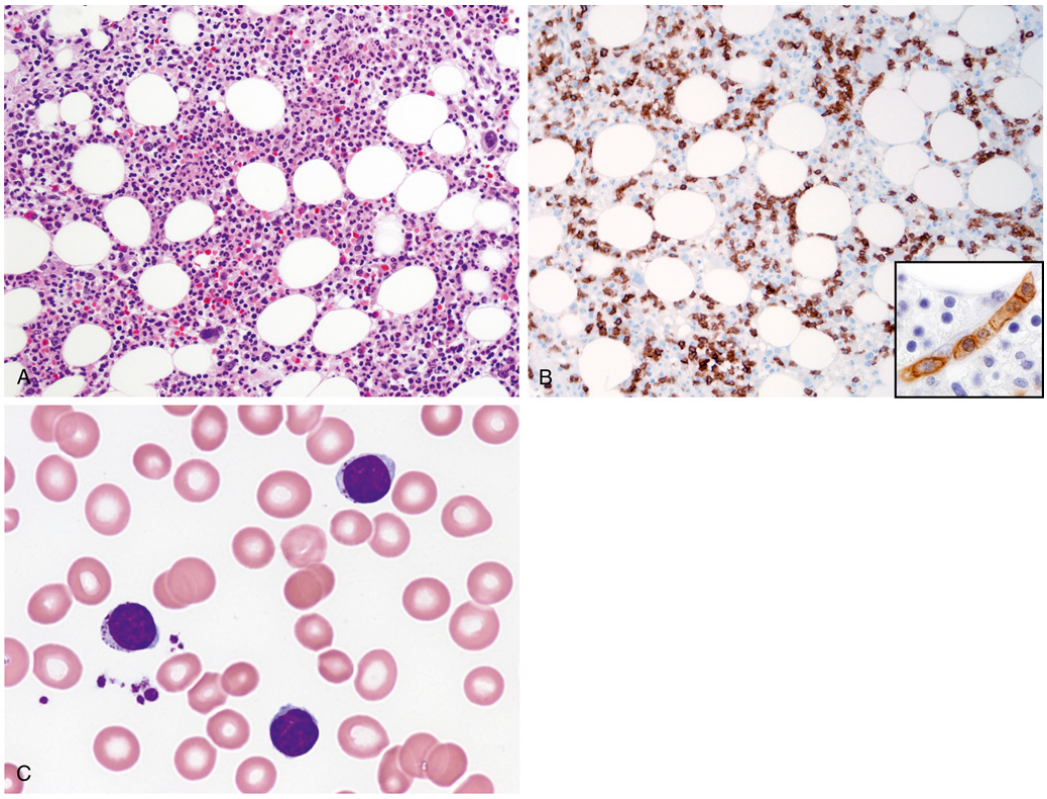

FIGURE 55-32 T-cell large granular lymphocytic leukemia involving the bone marrow.**A,** The T-cell large granular lymphocytic leukemia (T-LGLL) infiltrates are subtle and difficult to appreciate on hematoxylin and eosin (H&E)–stained bone marrow section. **B,** Immunohistochemical staining for CD3 highlights the T-LGLL infiltrate with interstitial and intrasinusoidal infiltration characterized by a short, linear array of small lymphocytes within the sinusoids *(inset)*. **C,** The T-LGLL cells do not show cytologic atypia, and are indistinguishable from normal LGL. This case has clinical features and immunophenotype consistent with T-LGLL,

and molecular analysis was positive for a clonal TCR gene rearrangement.

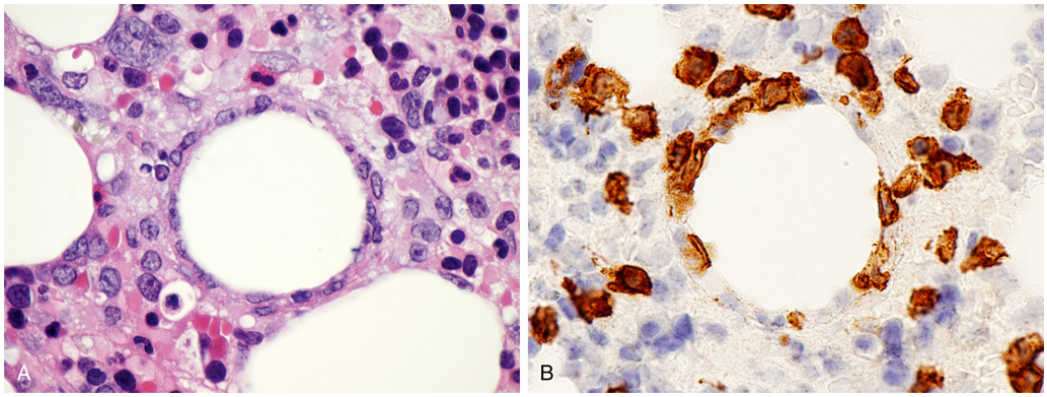

FIGURE 55-33 Subcutaneous panniculitis-like T-cell lymphoma involving the bone marrow.**A,** The bone marrow core biopsy shows focal lymphoid infiltrates with prominent rimming of the fat cells, similar to the pattern in the subcutaneous site. **B,** Immunohistochemical staining for CD8 is positive in the neoplastic cells.

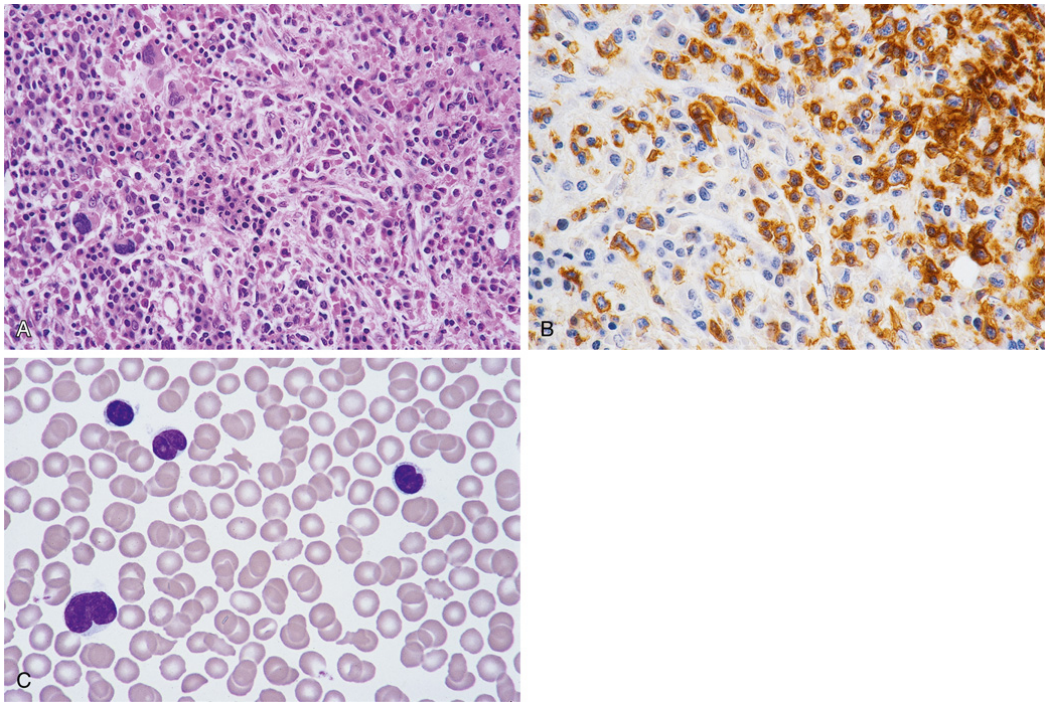

FIGURE 55-34 Cutaneous T-cell lymphoma/Sézary syndrome involving the bone marrow and peripheral blood.**A,** The bone marrow core biopsy shows focal lymphomatous infiltrate in loose stroma, with poorly demarcated borders. **B,** Immunohistochemical staining for CD3 accentuates the variably sized T cells within the infiltrate. **C,** Lymphoma cells in the peripheral blood vary in size but are often larger than normal lymphocytes and have convoluted, “cerebriform” nuclei, less condensed chromatin, and indistinct nucleoli.

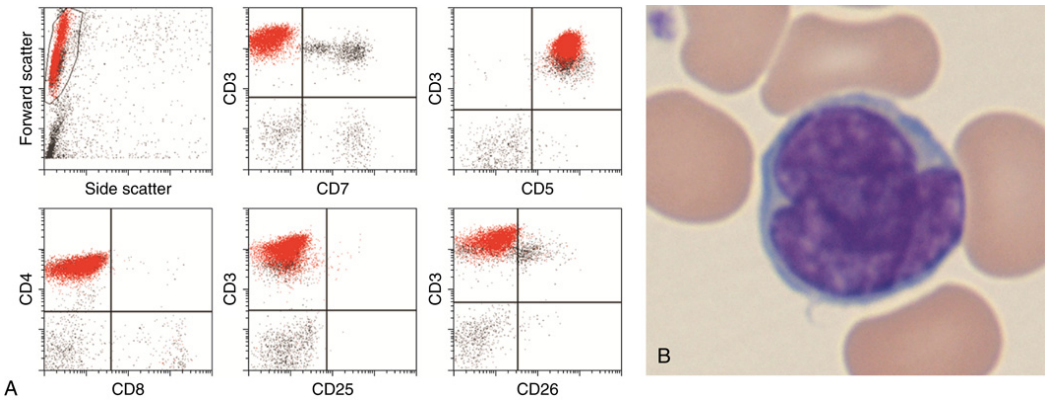

FIGURE 55-35 Sézary syndrome.**A,** Flow cytometric immunophenotyping demonstrates a $CD3^+$ T-cell population *(red)* with an aberrant T-cell phenotype: $CD3^+$, $CD5^+$, $CD7^-$, $CD4^+$, $CD8^-$, $CD25^-$, and $CD26^-$. **B,** High-power view of a Sézary cell in the peripheral blood smear.

T-Follicular Helper Cell Lymphoma

T-follicular helper (TFH) cell lymphoma include three subtypes: angioimmunoblastic, follicular, and not otherwise specified (NOS), which share a TFH cell immunophenotype and a common genetic landscape.[65,66] TFH-angioimmunoblastic type, previously designated angioimmunoblastic T-cell lymphoma (AITL), is the prototype of TFH cell lymphoma with well-defined morphologic, immunophenotypic, and molecular features. TFH-angioimmunoblastic type involves the bone marrow in about 50% to 80% of cases.[20,185,186] The infiltrates are generally identified by their hypocellularity in contrast to the surrounding hypercellular marrow. The lesions are typically focal random and multiple. Paratrabecular infiltration is also common, but diffuse infiltration is rare. The infiltrates are heterogeneous, consisting of a variable

number of lymphocytes, plasma cells, immunoblasts, histiocytes, and eosinophils; small blood vessels may be prominent (**Fig. 55-36**). Neoplastic cells with clear cytoplasm typically seen in the extranodal sites are usually not common in the bone marrow biopsy. In some cases, the prominent plasmacytosis may obscure the neoplastic infiltrates.[185] Circulating plasma cells, plasmacytoid lymphocytes, or immunoblasts are present in about one-third of patients, but cytologically overt malignant cells are uncommon in the blood or bone marrow smears.

TFH cell lymphoma is derived from the T-follicular helper cells that normally reside in the germinal centers. Similar to their normal counterpart, the tumor cells are positive for CD3, CD4, CD10, BCL6, ICOS, PD-1, and CXCL13; EBV is positive in about 75% of cases.[65,66] However, immunohistochemical staining for these markers on a bone marrow biopsy is less helpful compared with lymph node because of different microenvironment and relatively small number of tumor cells (e.g., the expression of follicular T-helper–associated markers, CXCL13 and CD10, is much lower in the bone marrow than in the lymph node).

The differential diagnosis of TFH cell lymphoma in the bone marrow includes HL, THRLBCL, peripheral T-cell lymphoma, NOS, and non-neoplastic lymphohistiocytic lesions. In general, HL and THRLBCL can be excluded by examining multiple levels of bone marrow section and immunohistochemical studies. Although bone marrow findings, in conjunction with clinical presentations, may suggest a diagnosis of TFH cell lymphoma, a primary diagnosis based on the bone marrow findings alone can be extremely challenging and should not be made without the right clinical

context. Demonstration of a sCD3-negative/CD4-positive/CD10-positive T-cell aberrant population and common mutations seen in TFH cell lymphoma, such as *TET2* and *RHOA* mutations, are features that are relatively specific for a TFH cell neoplasm.[187,188] The details of morphologic features of three subtypes of TFH cell lymphoma and mutational profiles can be found in Chapter 35.

Peripheral T-Cell Lymphoma, Not Otherwise Specified

Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) involves the bone marrow in about 20% to 40% of cases at diagnosis.[46,189-192] The bone marrow infiltrates are often diffuse or focal random.[163,193,194] As with many other PTCL, the lesions tend to be less sharply demarcated than B-cell lymphomas and intercalate into the surrounding bone marrow (**Fig. 55-37**). The bone marrow infiltrates are often polymorphous, containing abnormal lymphocytes admixed with reactive polymorphous infiltrates, including plasma cells, histiocytes, and eosinophils; prominent vascularity and reticulin fibrosis may also be present in the lesions.[193,194] The cytology of the neoplastic cells is variable but frequently similar to the primary site. They range from small-to-large in size, often with irregular and hyperchromatic nuclei. Occasional cases consisting of a monotonous population of medium-to-large cells or containing large, pleomorphic cells can also be seen.

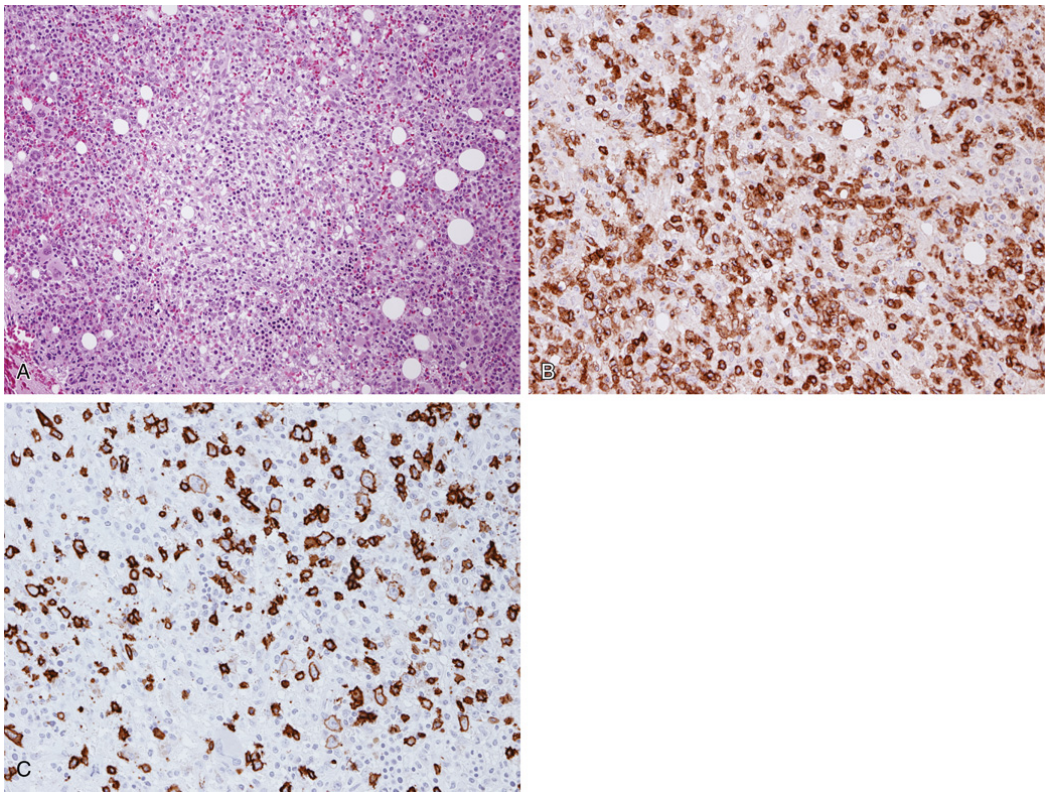

FIGURE 55-36 T-follicular helper cell lymphoma, angioimmunoblastic type, involving the bone marrow.**A,** The infiltrates are heterogeneous with poorly defined borders. The neoplastic cells with clear cytoplasm typically seen in the lymph node biopsy are uncommon in the bone marrow, but are present in this case. **B,** Immunohistochemical staining for CD3 highlights frequent small-to-medium-sized T cells. **C,** Immunohistochemical staining for CD20 shows a moderate number of reactive B cells, which vary from small to large, transformed cells (immunoblasts).

Lymphoma cells are present in the aspirate smears in most cases (70%) when bone marrow is involved; they vary from occasional to numerous and are morphologically similar to those in the bone marrow core biopsy sections, with the exception of large lymphoma cells that are usually rare in the aspirate. Circulating lymphoma cells are present in about 30% of cases; rarely, a marked leukocytosis is present.[194]

Anaplastic Large Cell Lymphoma

Anaplastic large cell lymphoma (ALCL) involves the bone marrow in about 10% to 30% of cases.[46,47,190,192,195,196] The incidence of marrow involvement by ALK-positive and ALK-negative ALCL is 9% and 13%, respectively, in a large series.[46] The infiltrates are focal random, interstitial, intrasinusoidal, or occasionally diffuse. The lymphoma cells may also occur as small clusters or isolated single cells that are often difficult to identify on H&E-stained bone marrow sections, but immunohistochemical stains for CD30 and ALK1 can highlight these subtle infiltrates (**Fig. 55-38**). In one study, lymphoma cells were found by immunohistochemical staining in 23% of patients with negative bone marrow by routine histology.[195] It is important to identify bone marrow involvement by ALCL, even when subtle, because it is associated with a poor prognosis. The lymphoma cells are large but variably sized with irregular nuclei, dispersed chromatin, multiple prominent nucleoli, and abundant basophilic cytoplasm. In occasional cases, the lymphoma cells can be found in the peripheral blood (**Fig. 55-38**). Rare cases with numerous circulating lymphoma cells have also been reported.[197,198]

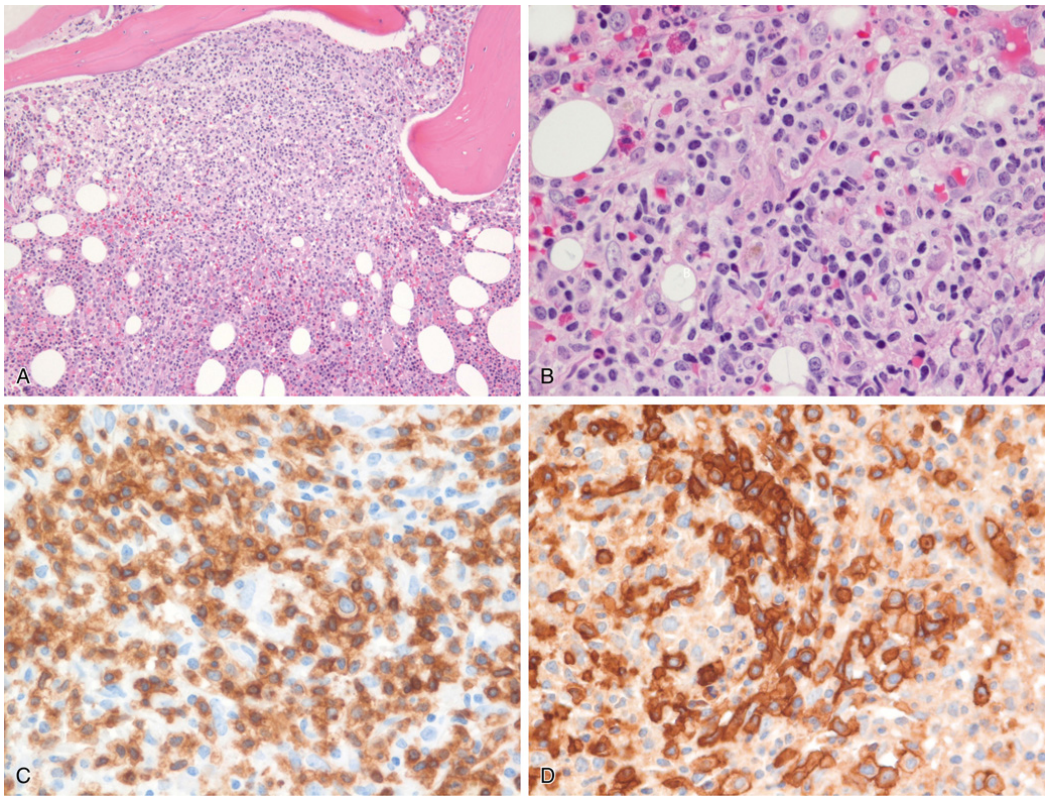

FIGURE 55-37 Peripheral T-cell lymphoma, not otherwise specified, involving the bone marrow.**A–B,** The hematoxylin and eosin (H&E)–stained bone marrow section demonstrates an abnormal lymphoid infiltrate with admixed inflammatory cells and many small blood vessels. **C,** Immunohistochemical staining for CD3 highlights the majority of lymphocytes within the infiltrate. **D,** PD1 is positive in number and distribution corresponding to CD3.

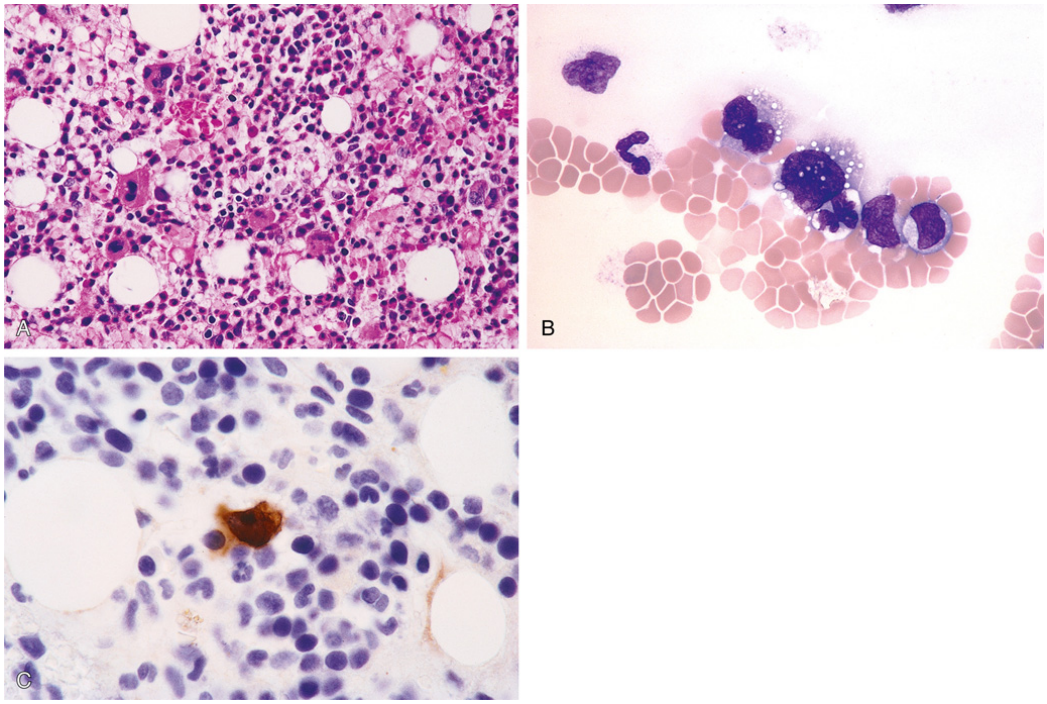

FIGURE 55-38 Anaplastic large cell lymphoma involving the bone marrow and peripheral blood.**A,** The lymphoma cells are not apparent on hematoxylin and eosin (H&E)–stained bone marrow core biopsy. **B,** Rare large lymphoma cells with cytoplasmic vacuoles are present at the feathered edge of the peripheral blood smear. **C,** One of the occasional lymphoma cells in the bone marrow highlighted by immunohistochemical staining for ALK1.

The differential diagnosis of ALCL in the bone marrow includes DLBCL, HL, and metastatic carcinoma. DLBCL can be easily excluded by negative staining for B-cell markers. In contrast to HL, ALCL usually lacks the inflammatory background and is negative for PAX5. ALCL may also mimic metastatic carcinoma when it forms cohesive clusters or sheets. A panel of immunohistochemical stains,

such as cytokeratin, ALK1, and T-cell markers, will help in the distinction.

Hodgkin Lymphoma Involving Bone Marrow

The overall incidence of bone marrow involvement by CHL is about 5% to 15% at diagnosis.[14,199,200] However, the frequency varies with the subtype. In a large study of 1161 patients with HL, the overall incidence of bone marrow involvement was 8%, but 19% in lymphocyte depleted, 14% in mixed cellularity, 4% in nodular sclerosis, and 2% in lymphocyte predominant type.[11] The study also showed that bilateral bone marrow biopsies increased the detection rate because the lymphoma cells were identified only in one of the bilateral biopsies in 35% (19 of 51) of patients.

In rare cases, bone marrow is the primary diagnostic site in HL. This occurs most frequently in patients with AIDS,[201-203] and HL is restricted to the bone marrow at diagnosis in approximately 14% of cases.[203] These patients usually lack lymphadenopathy and do not develop HL at extramedullary sites during the disease course.

If bone marrow is assessed, the bone marrow core biopsy is the procedure of choice for the diagnosis or staging of HL. The aspirate is insensitive for the detection of HL.[204] Reed-Sternberg cells are usually absent in the aspirate smears, although they can be identified in rare cases with extensive bone marrow involvement. HL in the bone marrow is characterized by discrete, space-occupying lesions that are usually clearly demarcated from the surrounding normal bone marrow. Focal involvement is present in about 30% of cases; the infiltrates may be single or multiple, random, or paratrabecular.

Diffuse bone marrow involvement has been reported in about 70% of cases (**Fig. 55-39**).[14] The infiltrates are polymorphous and frequently contain a prominent component of small lymphocytes, and variable numbers of plasma cells, histiocytes, and eosinophils (**Fig. 55-40**). Reed-Sternberg cells or variants are almost always present, although in some cases, multiple sections must be examined to identify the neoplastic cells. Fibrosis is almost always present in the infiltrate and may be prominent, especially in diffuse lesions. Necrosis may be present and is more common in treated patients.

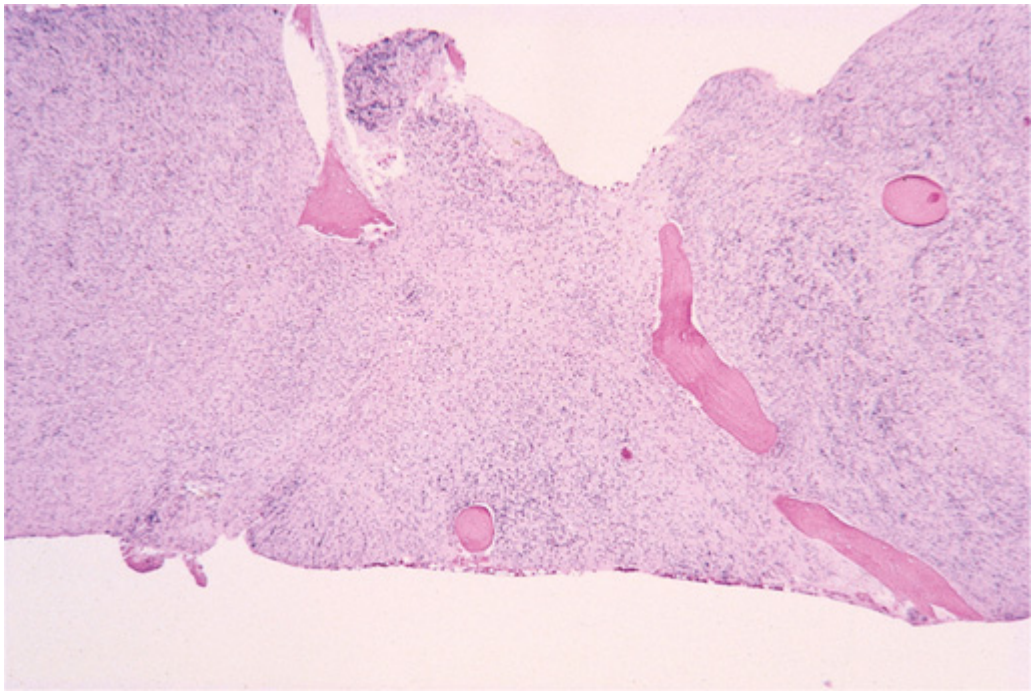

FIGURE 55-39 Hodgkin lymphoma involving the bone marrow.This case shows extensive bone marrow involvement by Hodgkin lymphoma that completely replaces the normal hematopoietic tissue.

Historically, the criteria for diagnosing HL in the bone marrow vary, depending on whether the bone marrow was the initial diagnostic site.[205,206] In current practice, when abnormal large cells with the characteristic immunophenotype of Hodgkin cells ($CD30^+$, $CD15^{+/-}$, $CD45^-$, $CD3^-$, $CD20^-$/variably$^+$, $PAX5^+$, $ALK1^-$) are identified in the bone marrow in a cellular background typical for HL, detection of morphologically classic Reed-Sternberg cells is not always necessary for a primary diagnosis of HL. However, subclassification of HL in a bone marrow biopsy is not encouraged as the small sample size and variability of histopathology between lymph node and bone marrow make subclassification unreliable.[205] The uninvolved bone marrow in patients with HL frequently exhibits reactive changes, including granulocytic hyperplasia, eosinophilia, and increased numbers of megakaryocytes. These findings can be confused with an MPN, particularly when the patient does not have an established diagnosis of HL.

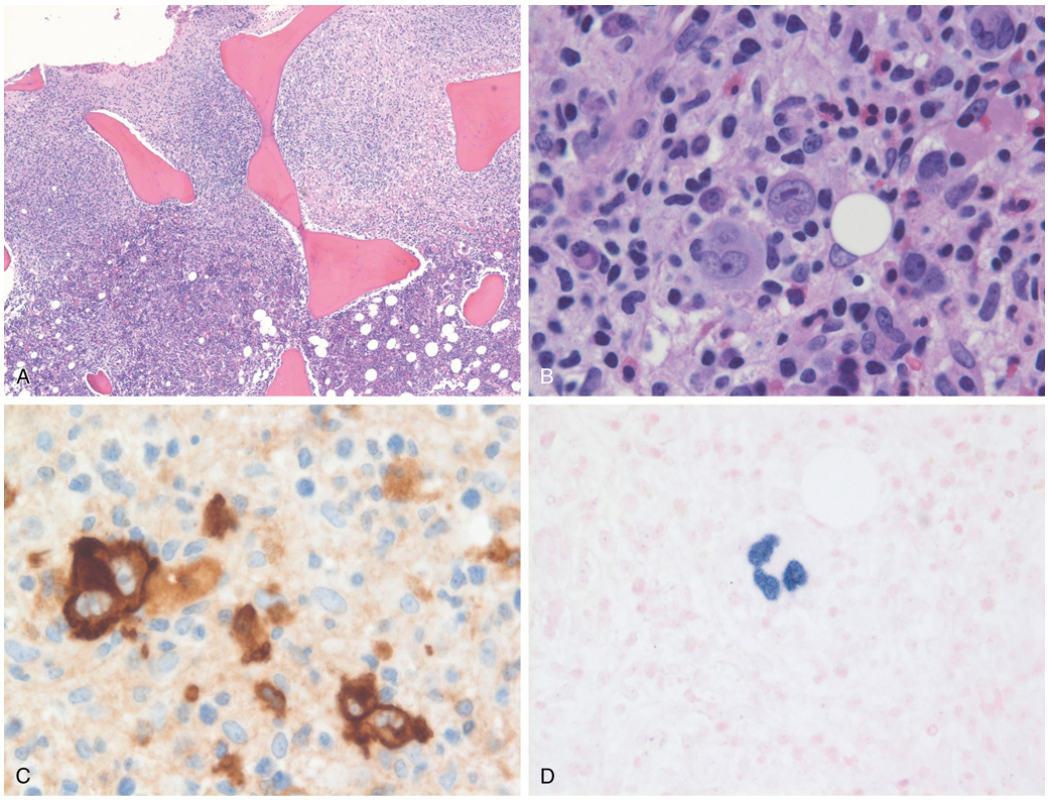

FIGURE 55-40 Hodgkin lymphoma involving the bone marrow.**A–B,** The bone marrow shows abnormal infiltrates that are polymorphous and contain Reed-Sternberg cells in a background of small lymphocytes, histiocytes, plasma cells, neutrophils, and occasional eosinophils. **C–D,** The neoplastic cells are positive for CD30 **(C)** and EBER **(D)**.

Nodular lymphocyte predominant HL (NLPHL) remains a subtype of HL in the 2022 WHO classification but is classified as a subtype of B-cell lymphoma, nodular lymphocyte predominant B-cell lymphoma (NLPBCL), in the ICC classification given its well-recognized germinal center B-cell origin.[65,66] NLPHL/NLPBCL rarely involves the bone marrow. In a large series of 275 patients

with NLPHL of pure nodular pattern, bone marrow involvement was identified in 7 (2.5%) patients, including 4 (1.5%) at the initial diagnosis and 3 during therapy or at relapse.[207] The bone marrow was involved by large B cells (<10% cells) associated with a prominent T-cell and histiocytic infiltrate in the background, and the bone marrow involvement was associated with a poor prognosis.[207]

Non-Hodgkin lymphomas, such as ALCL, THRLBCL, and PTCL, may mimic HL in the bone marrow. In addition, granulomas may be present in HL infiltrates and could be mistaken for a benign infiltrative process. HL must be differentiated from reactive polymorphous lymphohistiocytic lesions, which are commonly encountered in the bone marrow of patients with immunodeficiency such as AIDS.[208,209] Appropriate immunohistochemical stains often allow this distinction. In equivocal cases, biopsy of lymph node or other tissue are necessary for a definite diagnosis.

Nonlymphoid Malignancies That Mimic Lymphomas

Metastatic Tumors

Metastatic tumors in the bone marrow are usually easily distinguished from lymphoma because the malignant cells often occur as cohesive clusters (**Fig. 55-41**). However, tumor cells from small cell carcinoma and other small round blue cell tumors, such as embryonal rhabdomyosarcoma, neuroblastoma, retinoblastoma, and Ewing's sarcoma, can be present as discohesive cells in the aspirate smears and mimic lymphoma cells (**Fig. 55-41**).[210,211] Scanning the aspirate smear at low magnification is useful to identify cohesive clusters of tumor cells, even when they are rare. In the bone marrow

core biopsy, foci of metastatic tumor are almost always sharply demarcated from normal hematopoietic cells. Rarely, they focally infiltrate as groups of cells between hematopoietic cells and resemble lymphoma (**Fig. 55-42**). In other cases, the metastatic carcinoma may be extensive and diffusely replace the normal bone marrow. When the carcinoma cells are large and anaplastic, they can resemble a large cell lymphoma or HL (**Fig. 55-43**). Immunohistochemical stains appropriate for the tumor (e.g., cytokeratin, EMA, chromogranin, CD45, CD3, and CD20) performed on the bone marrow core biopsy or clot section can confirm the diagnosis of a metastatic tumor and exclude lymphoma.

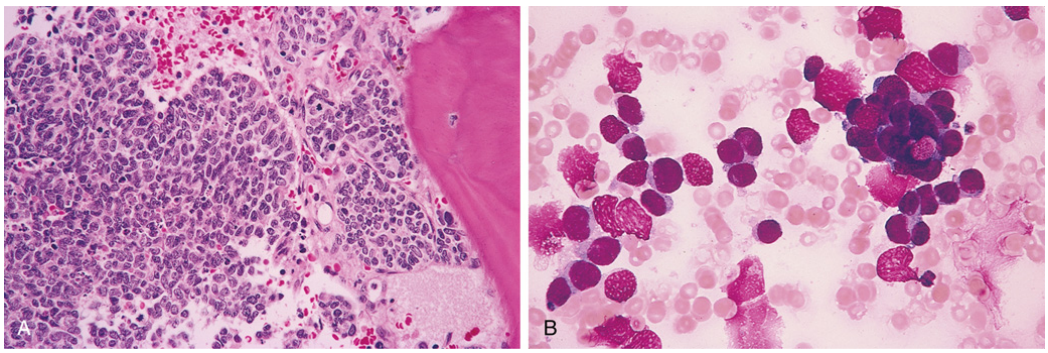

FIGURE 55-41 Metastatic neuroendocrine carcinoma in the bone marrow.**A,** Cohesive tumor cells in the bone marrow core biopsy. **B,** Discohesive, small carcinoma cells in the bone marrow aspirate smear resemble lymphoma cells; a small cohesive cluster of tumor cells, which is more typical of carcinoma, is also present.

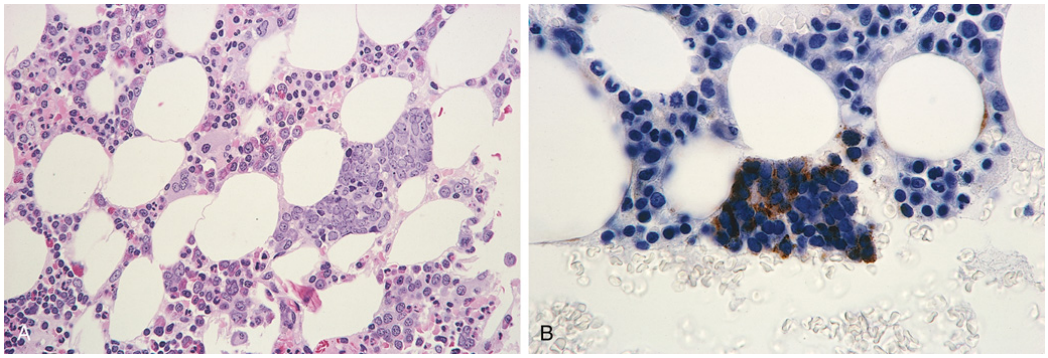

FIGURE 55-42 Metastatic neuroendocrine carcinoma in the bone marrow.**A,** Focal clusters of carcinoma cells with dispersed chromatin are nestled among the normal hematopoietic elements. The carcinoma cells superficially resemble a large cell lymphoma. **B,** Immunohistochemical staining for chromogranin is positive in the carcinoma cells.

Systemic Mastocytosis

Systemic mastocytosis involves the bone marrow in at least 90% of cases and shows similar patterns of infiltration as lymphoma, including paratrabecular, perivascular, random, or, rarely, diffuse infiltrates.[212] In most cases, the mast cell lesions in the bone marrow are polymorphous, and the mast cells are admixed with lymphocytes, eosinophils, neutrophils, histiocytes, endothelial cells, and fibroblasts in varying proportions. The polymorphous mast cell lesions can mimic lymphoma, particularly PTCL or HL. Occasionally, lymphocytes predominate and closely resemble non-Hodgkin lymphoma (**Fig. 55-44**). Recognition of mast cells in the bone marrow sections is critical to arrive at a diagnosis of systemic

mastocytosis because they can look like foci of paratrabecular fibrosis. The mast cells show variable morphology and may have round, oval, spindle-shaped, or monocytoid nuclei with abundant, slightly eosinophilic cytoplasm. One helpful morphologic clue to recognizing systemic mast cell disease in the bone marrow is the frequent compartmentalization of cells, with clusters of small lymphocytes surrounded by mast cells, creating the classic “bull’s eye” lesion.

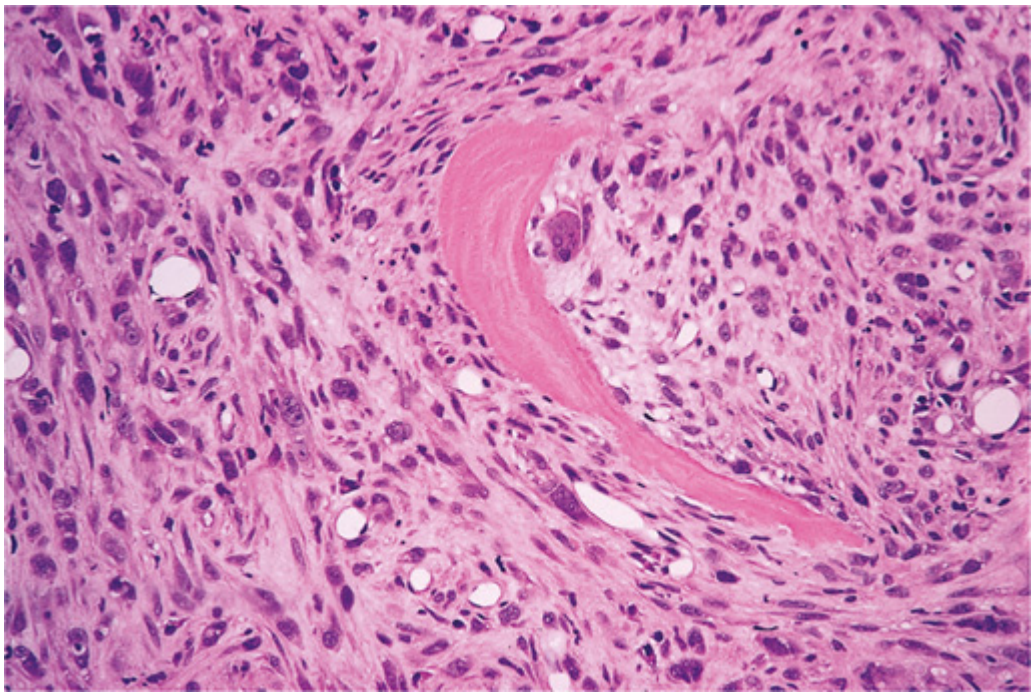

FIGURE 55-43 Metastatic carcinoma in the bone marrow.The metastatic carcinoma in this case is associated with marked fibrosis, and the tumor cells are large and anaplastic, resembling Hodgkin lymphoma. A cytokeratin stain (not shown) was positive in the tumor cells.

The most specific immunohistochemical stain for identifying mast cells is tryptase (**Fig. 55-44**). In addition, mast cells express CD117, CD45, CD33, and CD68, but are negative for CD3, CD20, and CD15.[213] Neoplastic mast cells also aberrantly express CD30, CD25, or CD2, which can help distinguish them from reactive mast cell hyperplasia.[213,214] Somatic mutations of *KIT,* a proto-oncogene that encodes the tyrosine receptor for stem cell factor (CD117), is found in the mast cells from patients with systemic mastocytosis.[215]

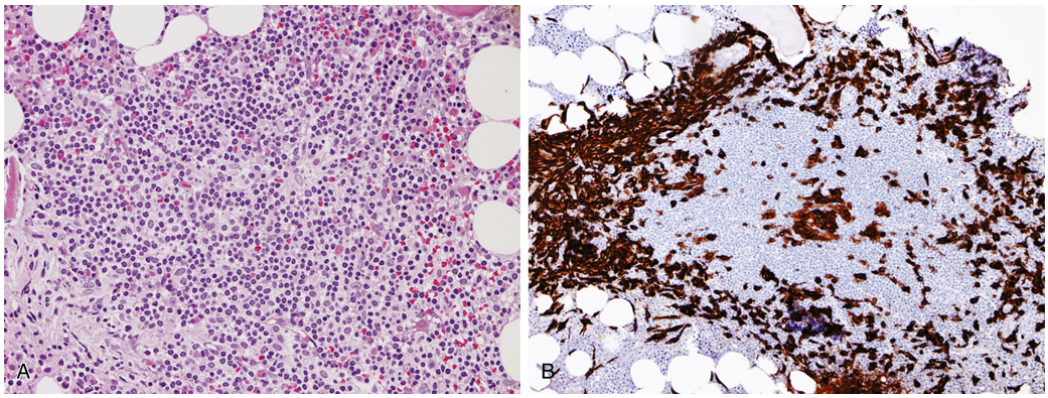

FIGURE 55-44 Systemic mastocytosis involving the bone marrow.**A,** The polymorphous infiltrates contain numerous small lymphocytes, occasional eosinophils, and small vessels, resembling a low-grade non-Hodgkin lymphoma. The mast cells are difficult to appreciate on hematoxylin and eosin (H&E)–stained section. Note the spindle-shaped mast cells with clear cytoplasm at the periphery of the lesion. **B,** Immunohistochemical staining for tryptase highlights the mast cells surrounding the lymphoid aggregate.

Pearls and Pitfalls

Pearls

- Benign lymphoid aggregates are usually small, well-circumscribed, and contain a heterogeneous cellular population.

- Reactive germinal centers usually indicate benign lymphoid infiltrate and are most commonly seen in patients with autoimmune diseases.
- Benign lymphoid aggregates often have a mixture of B and T cells, often with T-cell predominance.
- Distinct paratrabecular lymphoid infiltrates almost always indicate lymphoma, are most commonly associated with follicular lymphoma, and essentially exclude chronic lymphocytic leukemia (CLL)/small lymphocytic lymphoma (SLL).
- Intrasinusoidal lymphoid infiltrate usually indicates a neoplastic process and commonly associated with intravascular large B-cell lymphoma, splenic marginal zone B-cell lymphoma, hepatosplenic T-cell lymphoma, and T-cell large granular lymphocytic leukemia.
- Lymphoma-specific immunohistochemical markers (e.g., ALK1, LEF1, cyclin D1, and SOX11) and molecular cytogenetic abnormalities (e.g., *MYD88* mutation) are helpful in distinguishing benign versus neoplastic lymphoid infiltrate, as well as in subclassification of lymphoma.

Pitfalls

- Lymphoma, particularly T-cell types, can be morphologically heterogeneous and mimic a reactive process in the bone marrow.
- Reactive germinal centers are present in about 30% of splenic marginal zone lymphomas in the bone marrow.

- Exclusively paratrabecular lymphoid infiltrates can occasionally be present in mantle cell lymphoma.
- Paratrabecular lymphoid infiltrates may remain after anti-CD20 therapy for follicular lymphoma but may be composed entirely of T cells, which mimic residual follicular lymphoma.
- Intrasinusoidal infiltrates are difficult to appreciate on hematoxylin and eosin (H&E)–stained sections; immunohistochemical stains are helpful in highlighting the infiltrates.
- Anaplastic large cell lymphoma and nasal-type natural killer (NK)/T-cell lymphoma can infiltrate the bone marrow as isolated single cells; immunohistochemical stains can increase the detection rate.
- Diffuse large B-cell lymphoma may show a discordant lymphoma subtype in the bone marrow, often characterized by a low-grade lymphoma (most commonly follicular lymphoma).
- Low-level monoclonal B-cell populations may be identified in the peripheral blood or bone marrow in “healthy” individuals without evidence of lymphoma.
- Clonal T-cell populations can be detected in various benign conditions, particularly in autoimmune diseases.

Chapter 56: Evaluation of the Bone Marrow After Therapy

Heesun J. Rogers, Megan Nakashima, Sindhu Cherian, and Wayne Tam

OUTLINE

Effects of Selected Therapies and Bone Marrow Transplantation

- **Chemotherapy**
- **Bone Marrow Transplantation**
- **Recombinant Cytokine Therapy**
- **Other Selected Therapies**

Acute Leukemia or Myelodysplastic Syndrome

- **Acute Myeloid Leukemia and Myelodysplastic Syndrome**
- **Acute Lymphoblastic Leukemia**

Chronic Myeloid Leukemia

- **Morphologic Features**
- **Immunophenotyping**

Cytogenetics and Molecular Studies

BCR::ABL1-Negative Myeloproliferative Neoplasms

Morphologic Features

Immunophenotyping

Cytogenetics and Molecular Studies

Chronic Lymphoproliferative and Plasma Cell Disorders

Morphologic Features

Immunophenotyping

Cytogenetics and Molecular Studies

Other Bone Marrow Changes after Therapy

Necrosis

Fibrosis

Serous Atrophy/Gelatinous Transformation

Solid Tumors

Late Effects of Therapy, Including Secondary Malignancies

Given the variety of therapies currently in use for hematologic diseases, knowledge of the many changes these therapies can induce in the bone marrow is necessary, both to determine therapy effectiveness and to avoid overinterpretation of reactive changes.

Multiple therapies can cause changes in the marrow that may mimic malignancy, including chemotherapy with or without radiation, recombinant cytokines and colony stimulating factors, and bone marrow or hematopoietic stem cell transplantation. Serial bone marrow studies at prescribed intervals according to protocols during and after therapy are important for evaluation of residual disease, effectiveness of therapy, and regeneration of hematopoietic cells. After transplantation, an examination to confirm engraftment needs to be performed.

Optimal materials for evaluating post-therapy changes include a peripheral blood smear, bone marrow aspirate, touch preparations (imprints), and trephine biopsy sections. However, clot biopsy sections may also be useful, in particular if further molecular DNA or RNA studies are necessary. Extracted DNA and/or RNA or buffy coat preparations can also be used for further molecular genetic studies. An aspirate containing several marrow particles paired with core biopsies with a good length (greater than 1.5 cm or 10 partially preserved intertrabecular areas) are adequate material for a morphologic evaluation and ancillary tests.[1,2] Aspirate smears and touch imprints generally offer the best cytologic detail and are helpful in evaluating residual blasts after therapy. Biopsy material is useful for showing the pattern of blast distribution, once they are identified on the aspirate material, and the presence and pattern of residual lymphoma or solid tumor involvement. Ancillary studies are often of critical importance in the evaluation of post-therapy bone marrow specimens, particularly in the assessment of residual disease. These studies include flow cytometry, immunohistochemistry, and cytogenetic and molecular genetic

studies. With the exception of immunohistochemistry and some molecular genetic tests, additional fresh bone marrow aspirate specimens are required to detect persistent or minimal residual disease. In addition, complete clinical information—including information about the primary disease process, type of treatment, and time interval since treatment—should be submitted with the bone marrow specimen.

This chapter describes the general effect of selected therapies, including hematopoietic stem cell transplantation, on the bone marrow and discusses the morphologic changes in the bone marrow at early and late intervals after therapy, including therapy-related neoplasms. The utility of ancillary studies, including flow cytometry, cytogenetics, and molecular genetic studies for follow-up of specific hematologic neoplasms post-therapy, is also covered.

Effects of Selected Therapies and Bone Marrow Transplantation

Chemotherapy

Several studies have evaluated bone marrow changes in acute leukemias after high-dose chemotherapy, with or without radiation, or after bone marrow or hematopoietic stem cell transplantation,[1,3-8] and there are many similarities in the findings (**Box 56-1**; **Fig. 56-1**). These changes are similar to the toxic changes resulting from drug/toxin injury of the bone marrow.[9,10] The extent and duration of changes can be influenced by various factors such as drugs, pharmacogenomics, dosage of drugs, or the neoplastic cells.

Morphologic changes in the marrow caused by chemotherapy are related to accelerated cell death in response to cytotoxic therapy and

the subsequent reconstitution of hematopoietic cells.[2,3,6] Early changes expected in the first week after myeloablative treatment include decreased cellularity as a result of death of neoplastic and nonneoplastic cells to complete marrow aplasia. Peripheral cytopenias will occur at the same time. The marrow cellularity is often nearly zero, with an absence of normal marrow fat. There is prominent stromal edema, with dilated marrow sinuses. Scattered stromal cells, histiocytes, plasma cells, and lymphocytes may be present. Deposition of pink proteinaceous material may be seen, which can mimic fat serous atrophy (gelatinous transformation, discussed later in this chapter), but the presence of the eosinophilic gelatinous material of serous atrophy has only rarely been reported after chemotherapy. Normal hematopoietic cells, such as maturing granulocytes, nucleated red blood cells, and megakaryocytes, are often not identifiable. Phagocytic macrophages containing cellular debris are often present, and acellular areas of pink-staining fibrin and fibrinoid necrosis often predominate. Rare cases may also show zonal areas of tumor cell necrosis or foci of residual tumor cells.[2,3]

Signs of early regenerating marrow begin with reappearance of fat cells, and development of mild transient reticulin fibrosis follow these changes.[2,3,8,11] The early fat in regenerating bone marrow is often loculated. Although the marrow remains markedly hypocellular, the fat is associated with focal areas of early hematopoiesis in the 2nd week after treatment. This may be represented by islands of erythroid cells, alone or in combination with areas of immature cells and left-shifted granulocytes (sheets of promyelocytes) in the paratrabecular area. Both elements are usually present after 2 weeks. Megakaryocytes, often occurring in clusters

(groups of 3–5) with atypical or hypolobated nuclei, occur later in this process but are usually easily identified by the 3rd week.[4,8] In some patients, particularly children, early regeneration may be accompanied by an increase in precursor B cells, or hematogones. The features of these cells are discussed later in this chapter. As the bone marrow continues to repopulate and returns to normal age-adjusted cellularity, loss of the mild reticulin fibrosis of early regeneration and even a slightly increased marrow cellularity may be seen. All three normal marrow cell lines are present, although a left shift of granulocytes and erythroid cells and atypical megakaryocyte clustering may persist for some time. Distinguishing regenerative atypical changes after therapy from persistent neoplastic myelodysplastic features is always a diagnostic challenge for pathologists.[9]

Box 56-1 Bone Marrow Changes in the 3 to 4 Weeks After Myeloablative Therapy

Initial Changes

- Hypocellularity to marrow aplasia
- Absence of fat cells
- Edema
- Fibrinoid necrosis
- Dilated sinuses
- Rare stromal cells, histiocytes, lymphocytes, and perivascular plasma cells

Intermediate Changes

- Reappearance of fat, often lobulated
- Mild transient reticulin fibrosis
- Foci of left-shifted erythroid and granulocyte islands
- Increase in precursor B cells or hematogones on smears

Late Changes

- Resolution of reticulin fibrosis
- Appearance of small megakaryocytes in clusters
- Normal or slightly increased marrow cellularity

In some cases, regeneration may be accompanied by findings such transiently increased blasts or hematogones, marked increase in regenerating, left-shifted granulocytes (particularly in promyelocyte stage), and/or increased megakaryocytes. A prolonged delay in regeneration of bone marrow, particularly in elderly patients, can be seen after chemotherapy in some cases.[2,9,12,13]

Bone Marrow Transplantation

Some additional bone marrow changes may be observed in patients who have undergone bone marrow or hematopoietic stem cell transplantation after high-dose therapy (**Box 56-2**).[2,3,8,9]

The sequential morphologic changes from early transplantation until day 28 after transplantation typically show findings similar to those seen in the bone marrow after receiving high-dose chemotherapy; these include hypocellularity to marrow aplasia, extensive cellular necrosis, stromal damage and edema, fat necrosis,

and hemophagocytic macrophages. Approximately 7 days after transplantation, foci of regeneration may be seen and can occur earlier in patients treated with stem cell infusion. Although clusters of regenerating marrow elements usually show a spectrum of maturation, these islands of cells may have a more monotonous appearance, without obvious maturation, after transplantation. This is most commonly seen with erythroid precursors. Early regeneration of marrow begins with appearance of small colonies of immature precursors (erythroid and granulocytic), often away from the bone (nonparatrabecular area) after transplantation. In comparison, immature granulocyte islands of blasts and promyelocytes usually occur adjacent to bony trabeculae (paratrabecular area) in normal marrow and in regenerating marrow after cytotoxic therapy. The presence of such islands away from the bone is considered an abnormal feature, referred to as abnormal localization of immature precursors (ALIP), and is described as a feature of myelodysplastic syndrome (MDS) on biopsy sections. After hematopoietic stem cell transplantation, these immature cell islands often occur away from the bone, and this feature should not be considered evidence of recurrent or impending MDS (**Fig. 56-2**).[14,15]

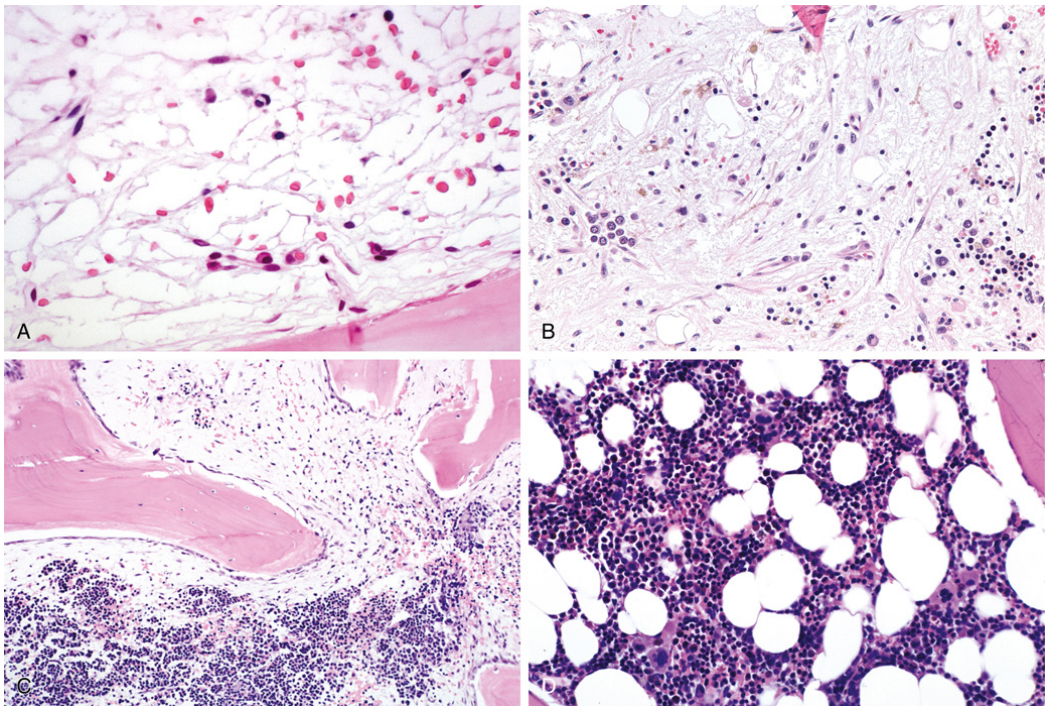

FIGURE 56-1 Bone marrow changes of myeloablative therapy.A, The marrow is initially acellular, with loss of fat cells. **B,** Islands of erythroid and granulocyte precursors then appear. **C,** The cellularity is often patchy, with acellular areas and areas of left-shifted cells. The hypocellular areas of this marrow still show mild fibrosis, which resolves as hematopoiesis returns. **D,** At 3 to 4 weeks, marrow cellularity returns.

Box 56-2 Post-Therapy Bone Marrow Changes

Unique to Hematopoietic Stem Cell Transplantation

- Regenerative islands with a monotonous, immature appearance
- Localization of immature cell precursors away from bony trabeculae (nonparatrabecular area)
- Increased storage iron and siderotic iron with or without ring sideroblasts
- Prolonged variable cellularity with or without cytopenias
- Prolonged aplasia resulting from engraftment failure
- Increased large granular lymphocytes

Bone marrow cellularity approaches 50% to 100% of normal by day 21 to day 28. Although engraftment is affected by many variables, including dose of infused cells, source of donor cells, and degree of HLA mismatch, engrafted trilineage hematopoiesis with normal cellularity is expected by day 28.[3,16] Transient dysplastic features in erythroid and granulocytic cells associated with chemotherapy may be seen.[9] Transient fibrosis and fibrinoid necrosis may be observed.[3] Increases in bone marrow iron storage or siderotic iron incorporation are also common findings after hematopoietic stem cell transplantation. This is usually apparent by an increase in hemosiderin-laden macrophages on both aspirate smears and trephine biopsy sections. Although the increase in siderotic iron is usually less uniform than that seen in refractory anemia with ring sideroblasts, in some cases, the pattern of iron staining may be similar or identical to that of sideroblastic anemia; therefore, iron stains must be interpreted with caution in post–marrow transplant patients.[17]

In some patients, bone marrow cellularity may never return to the normal range after hematopoietic stem cell transplantation. These patients frequently exhibit variability in marrow cellularity and often have a persistently hypocellular marrow that may be accompanied by mild peripheral blood cytopenias for many years. Prolonged impairment of hematopoiesis has been demonstrated after both standard and high-dose chemotherapy followed by bone marrow transplantation.[18,19] A hypocellular post-treatment marrow may result from bone marrow failure after solid organ or hematopoietic stem cell transplantation, failure to engraft after transplantation, or delayed engraftment after transplantation. The bone marrow in these patients is similar and shows signs of aplasia, even after several weeks, with predominance of stromal cells, histiocytes, lymphocytes, and plasma cells. Delayed engraftment may occur in patients with marked marrow fibrosis before transplantation, and diffuse histiocytic proliferations.[20,21] Graft failure after hematopoietic stem cell transplantation or bone marrow failure after solid organ transplantation may occur secondary to viral infection, reactivation of a virus, or hemophagocytic syndrome.[22-25] Late marrow failure may also occur as a terminal event of post-therapy MDS. The immunodeficiency associated with chemotherapy or transplantation also increases these patients' risk of developing infectious diseases. If an infectious disease is suspected, fresh bone marrow aspirate material should be sent for microbiology studies. Histochemical stains for acid-fast and fungal organisms should be performed on all biopsy specimens containing granulomas.

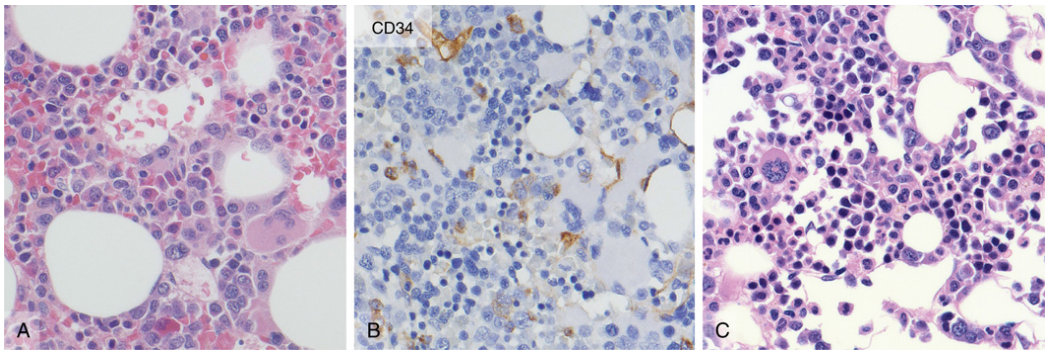

FIGURE 56-2 Although abnormal localization of immature precursors (ALIP) is a common neoplastic feature of myelodysplastic syndromes as shown by H&E (hematoxylin and eosin) in **(A)** and by CD34 immunostaining in **(B)**, in the case of patients after hematopoietic cell transplantation **(C)**, such myeloid maturation away from the bone is normal and should not be overinterpreted as evidence of myelodysplasia.

Recombinant Cytokine Therapy

Recombinant human cytokine factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF], interleukin [IL]2, IL3, IL11, erythropoietin, and thrombopoietin) are administered for a variety of reasons, including shortening cytopenic periods and enhancing bone marrow recovery after chemotherapy. In addition, such agents may be used to prime the marrow or peripheral blood before hematopoietic stem cell collection. It is essential that the administration of these agents be included in the clinical history of any patient undergoing bone marrow sampling.

The most commonly administered growth factors are human recombinant G-CSF and GM-CSF. Both peripheral blood and bone marrow alterations occur with these drugs (**Box 56-3**).[26-31] Both agents accelerate neutrophil recovery by 2 to 5 days and result in a peripheral blood leukocytosis with a left shift in granulocytes. Toxic granulation and Döhle bodies are often present and may give the appearance of a reactive proliferation. Enlarged neutrophils or neutrophils with vacuolated cytoplasm may also occur. The bone marrow shows a granulocytic hyperplasia (**Fig. 56-3**). Depending on the timing of bone marrow examination, the marrow may exhibit the complete spectrum of granulocytic maturation, have the appearance of maturation arrest, or show a predominance of segmented neutrophils. The maturation arrest–type changes that occur just after administration of growth factor pose the greatest challenge because they may be indistinguishable from recurrent leukemia or MDS. A predominance of promyelocytes (enlarged binucleated form) and myelocytes is usually present. In rare cases, bone marrow and even peripheral blood blasts may exceed 5%,[31] but this increase is usually accompanied by an increase in promyelocytes.[32] The transient increase in blast cells from growth factor administration should result in even higher numbers of promyelocytes; thus, blast proliferations that are not accompanied by an increase in promyelocytes should be considered highly suspicious for leukemia and not simply attributed to growth factor–derived changes. In a patient with a history of acute myeloid leukemia (AML), it may not be possible to entirely exclude the possibility of residual leukemia in the setting of an increase in blasts, and flow cytometric evaluation for immunophenotypic aberrancies and/or cytogenetic studies may be

useful in this setting. The promyelocytes that occur with G-CSF and GM-CSF therapy usually have prominent perinuclear hofs, and this feature should be a clue to the possibility of growth factor administration. These cells differ from those of acute promyelocytic leukemia,[33] which usually do not show perinuclear cytoplasmic clearing and demonstrate Auer rods, which are not present in reactive promyelocytes. Occasional giant tetraploid neutrophils are noted. In patients receiving GM-CSF, increased macrophages in the bone marrow and monocytosis in addition to hypercellular marrow involving trilineage hematopoietic cells may be present.[34] A repeat bone marrow examination 1 to 2 weeks after cessation of the growth factor usually demonstrates more complete granulocyte maturation, and such a study is advisable in cases suggestive of residual leukemia. If true leukemic blasts are present, they will persist or increase during this brief interval, whereas reactive growth factor changes will resolve with time. Less common changes reported after G-CSF and GM-CSF therapy include marrow necrosis[35] and marrow histiocytic proliferation,[34,36] which may be confused with metastatic tumors.[37]

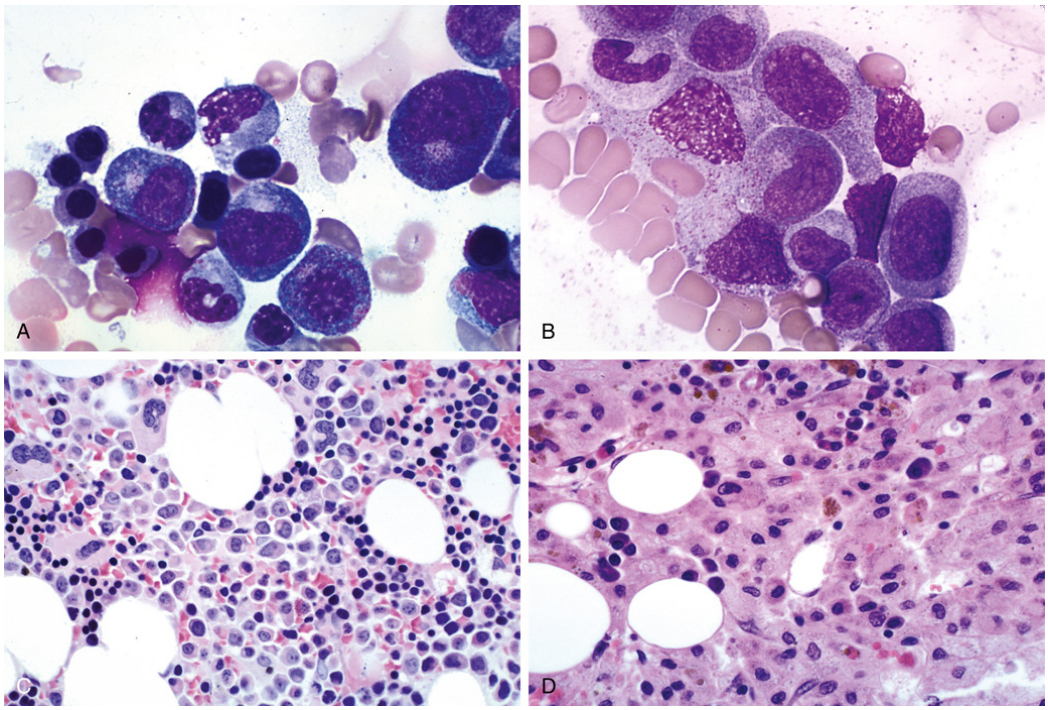

FIGURE 56-3 Bone marrow changes associated with granulocyte and granulocyte-macrophage colony-stimulating factors.A and **B,** Aspirate smears show an increase in promyelocytes with perinuclear hofs. **C,** Biopsy usually shows aggregates of left-shifted granulocytes. **D,** Rare cases show sheets of bone marrow histiocytes on the biopsy. These may be confused with metastatic tumor.

Box 56-3 Changes Associated With Recombinant Granulocyte Colony-Stimulating

Factor and Granulocyte-Macrophage Colony-Stimulating Factor Therapies

Peripheral Blood Changes

- Neutrophilia
- Granulocyte left shift
- Toxic granulation
- Döhle bodies
- Hypogranular neutrophils
- Vacuolated neutrophils
- Giant neutrophils
- Increase in large granular lymphocytes
- Eosinophilia
- Transient blast cells
- Circulating nucleated red blood cells

Early Bone Marrow Changes

- Granulocytic hyperplasia with an increased number of promyelocytes and myelocytes
- Transient blast-cell increase
- Toxic granulation of granulocytes
- Enlarged promyelocytes and myelocytes
- Increased macrophages (granulocyte-macrophage colony-stimulating factor [GM-CSF])
- Increased mitotic activity of granulocyte precursors
- Biopsy hypocellularity with left-shifted granulocytic precursors

Late Bone Marrow Changes

- Binucleated promyelocytes
- Marrow neutrophilia
- Marrow eosinophilia
- Toxic granulation
- Variable biopsy cellularity

IL2 infusion appears to result in granulocyte recovery by stimulating the natural production of GM-CSF.[38] IL3 appears to stimulate differentiation of even earlier progenitor cells than those of G-CSF and GM-CSF, resulting in an increase of all lineage cells (granulocytes, erythroid precursors, lymphoid cells, and megakaryocytes) and marrow cellularity. This agent also results in eosinophilia and may cause bone marrow fibrosis.[39] IL11 also stimulates proliferation of earlier progenitor cells and synergizes with IL3 and erythropoietin to promote erythropoiesis and megakaryopoiesis.[40]

Changes related to erythropoietin usually do not cause as much diagnostic confusion, and bone marrow studies are less commonly performed in patients taking this drug. Erythropoietin, which is given for various causes of red cell aplasia, including renal disease and aplastic anemia, usually results in a relative increase in marrow cellularity owing to proliferation of red blood cell precursors and maturation.[41-46] This red blood cell increase may result in a normal or decreased myeloid-to-erythroid ratio in the marrow. Patients who have erythroid hyperplasia from erythropoietin may also show mild nuclear irregularities and a left shift of the maturing erythroid cells.

The lack of dyspoietic changes in other cell lines is helpful in excluding MDS in this setting. Some patients with MDS treated with erythropoietin may actually show a relative decrease in erythropoiesis, presumably from a reduction in the degree of ineffective hematopoiesis.[45] Erythropoietin also stimulates megakaryopoiesis[46] and may result in megakaryocytic hyperplasia of the bone marrow. Rare patients who received erythropoietin have pure red cell aplasia caused by the development of anti-erythropoietin antibodies.[47]

Recombinant thrombopoietin may be given during or after chemotherapy, usually in combination with G-CSF or GM-CSF, to promote megakaryopoiesis and stimulate megakaryocyte precursors and platelet production.[48-50] Although peripheral blood platelets may increase to as high as $1000 \times 10^3/\mu L$, they are usually normal in appearance. Bone marrow cellularity increases in these patients, even compared with patients on GM-CSF alone, and the addition of thrombopoietin appears to increase the percentage of marrow granulocytes compared with GM-CSF alone. The megakaryocytic increase, however, is the most striking feature of thrombopoietin administration, with a subset of patients showing true megakaryocytic hyperplasia. The megakaryocytes are usually atypical, with a spectrum ranging from small hypolobated megakaryocytes with hyperchromatic nuclei to large megakaryocytes with hyperlobated nuclei. Intrasinusoidal megakaryocytes may also be present. The increase in megakaryocytes is usually associated with an increase in marrow fibrosis, and some patients have osteosclerosis. The atypical megakaryocytes may raise suspicion of MDS, but dysplastic changes are not seen in other cell lineages. A

subset of patients may have leukoerythroblastosis, with circulating megakaryocyte nuclei and thrombocytosis. Because these patients may also exhibit marrow hypercellularity with atypical megakaryocytic hyperplasia and bony sclerosis, it may not be possible to distinguish the changes related to thrombopoietin therapy from a myeloproliferative neoplasm (MPN), particularly primary myelofibrosis, without adequate clinical information. The lack of splenomegaly and the rapid resolution of the changes after discontinuing thrombopoietin are useful in this differential diagnosis. The nonpeptide thrombopoietin receptor agonist eltrombopag stimulates megakaryopoiesis and contributes to differentiation and increased platelet numbers.[51]

Pegylated recombinant human megakaryocyte growth and development factor has also been shown to increase bone marrow megakaryocyte production in normal individuals and in patients with aplastic anemia, MDS, and AML.[52,53] The effects are significantly increased when used in combination with other growth factors. The morphologic features of the bone marrow after administration of this agent are not well described.

Other Selected Therapies

Lenalidomide and derivatives, immunomodulatory agents, are used to treat MDS, plasma cell neoplasms, and some lymphomas.[54,55] In MDS, cytologic dysplastic features in all trilineage cell lines, blast count, and ring sideroblast percentage are reduced after therapy. The dysplastic hypolobated or nonlobated megakaryocytes noted in isolated 5q deletion are particularly decreased after therapy. Lenalidomide therapy can also lead to degenerative changes in

neoplastic plasma cells and increased apoptotic bodies and reduce neoplastic plasma cells. Lenalidomide is effective in treating some non-Hodgkin lymphomas as a single agent or in combination therapy via T-cell/natural killer (NK)-cell enhancement and antiproliferative effects.[54]

The tyrosine kinase inhibitor (TKI) imatinib and second-generation TKIs are highly effective first-line therapies for chronic myeloid leukemia. TKIs bind to the ABL domain of the BCR::ABL fusion protein, thereby preventing adenosine triphosphate (ATP) binding and inhibiting the fusion protein. Response to therapy (hematologic, morphologic, cytogenetic, and molecular) is monitored according to the National Comprehensive Cancer Network® (NCCN) guidelines.[56] Response is determined by the normalization of parameters in peripheral blood counts, decrease in the number of Philadelphia (Ph)-positive metaphases on cytogenetics, and decrease in the number of BCR::ABL1 mRNA transcripts by quantitative polymerase chain reaction (qPCR). After TKI therapy, the bone marrow shows morphologic changes, including reduced overall cellularity, reduced myeloid precursors and megakaryocytes, reduced severity of myelofibrosis, and regeneration in erythroid precursors. However, it can cause bone marrow hypoplasia, gelatinous transformation, pseudo Gaucher cells, or benign transient lymphoid nodules.[57]

Janus kinase (JAK) inhibitors (ruxolitinib, fedratinib) target JAK-associated signaling pathways for erythropoietin-mediated and thrombopoietin-mediated signaling and are used to treat MPNs, many immune-mediated and inflammatory diseases, and graft-versus-host disease. Most patients with MPNs have *JAK2* mutations

with upregulated JAK-STAT signaling. JAK inhibitors can reduce significant constitutional symptoms and splenomegaly and induce limited reversal of marrow fibrosis. Overall survival (OS) after JAK inhibitor therapy in primary myelofibrosis has improved. However, JAK inhibitors can often cause anemia and thrombocytopenia, which is most evident within the first 8 to 12 weeks of therapy.[58-61]

Rituximab, an anti-CD20 monoclonal antibody, is used to eradicate B cells in B-cell non-Hodgkin lymphomas or in some autoimmune or inflammatory disorders. It can be used as a single agent or in combination with other chemotherapeutic agents. The treatment is effective, particularly in a B-cell lymphoma expressing strong CD20.[62,63] However, after therapy with rituximab, bone marrow with involvement by a B-cell lymphoma may show lymphoid aggregates or lesions containing predominantly T cells.[64,65] Normal and neoplastic B cells can demonstrate a transient loss of CD20 expression after anti-CD20 therapy, and immunophenotypic evaluation after rituximab therapy (by flow cytometry or immunohistochemistry) will require other B-cell markers such as CD19, CD22, Pax5, or CD79a to find residual lymphoma. In some cases, a CD20-negative tumor subclone may emerge and lead to a CD20-negative relapse post–rituximab therapy. Rituximab can cause a self-limiting neutropenia with granulocytic maturation arrest, thrombocytopenia, and rarely, disseminate intravascular coagulation.[65-68] Additional markers such as CD19, CD22, and CD38 are now the targets of monoclonal antibodies, bispecific T-cell engaging antibodies, and CAR T cells. The effects of these will be discussed further in this chapter.

Acute Leukemia or Myelodysplastic Syndrome

With effective chemotherapy, the marrow is completely ablated, and bone marrow studies may be performed to confirm obliteration of the neoplastic process. Once the bone marrow has begun to regain cellularity with normal hematopoietic cells, the pathologist is faced with the challenge of evaluating for residual or recurrent disease. It is well established that the presence of minimal/measurable residual disease (MRD) that is undetectable by morphologic methods is a powerful predictor of recurrence. Although different types of acute leukemia offer their own unique problems, some general features are common to all cases. A blast count of 5% in the bone marrow is the historical cutoff for delineating the presence of residual or recurrent leukemia. However, this cutoff is arbitrary, and the current goal is to detect the presence of neoplastic clones as early as possible. The use of multiparameter flow cytometry and molecular genetic techniques to detect MRD is redefining remission in many diseases.[26,69-71] A general overview of the sensitivity of the methods used to detect MRD is given in **Table 56-1**. Knowledge of the advantages and disadvantages of different methods and appropriate selection of the appropriate method requires considering turn-around time, cost, availability, and standardization.[72]

The common use of growth factors can cause regenerative blast to increase above 5% in some cases. In this setting, it may be difficult to differentiate regenerating blasts from leukemic blasts by morphology. Therefore, decisions regarding relapse or remission should not be based on blast counts alone. When a blast population

in post-therapy bone marrow is suspicious for residual disease, comparison to the original acute leukemia is often helpful, and the presence of unique morphologic features such as Auer rods, distinctive cytoplasmic granules, prominent nucleoli, or nuclear irregularities that were identified in the original disease can be useful. In addition, the detection of an aberrant immunophenotype by flow cytometry is helpful. The immunohistochemical detection of immature CD34-positive or terminal deoxynucleotidyl transferase (TdT)-positive cells in clusters in a bone marrow biopsy is also helpful because immature cells in regenerating bone marrow do not normally show the clustering seen in recurrent leukemia specimens.

Surveillance of bone marrow is usually required to detect residual disease and recurrent disease, as most recurrence occurs within 1 to 3 years after the end of therapy. The detection of clonal cytogenetic abnormalities that were present in the patient's original leukemia can also be helpful in the evaluation of residual or recurrent disease.[26] Routine karyotype analysis or fluorescence in situ hybridization (FISH) studies are commonly used for this purpose. Ancillary testing is not necessary on all follow-up specimens. If residual or recurrent disease is suspected in the absence of material for these tests, such suspicion should be relayed to the treating physician. A repeat bone marrow evaluation after 1 or 2 weeks is often helpful to determine a change in the number of blasts, which would be expected to increase with recurrent disease, and appropriate ancillary tests can be performed on the second specimen. In contrast, increased immature cells in an early phase of marrow regeneration would be expected to show more mature precursors in the second bone marrow study.

Two common approaches to detect MRD with high sensitivity are multiparameter flow cytometry and molecular tests including qPCR for specific targets and next-generation sequencing (NGS)-based technologies. Knowledge of the immunophenotypic and genetic characteristics of a leukemia at diagnosis may facilitate assessment for residual or recurrent disease post-therapy, though it is not critical in all settings. Assessment of MRD after cycle 1 or 2 of induction chemotherapy can allow earlier identification of poor responders.[73,74]

Table 56-1

Sensitivity of Methods for Detecting Residual Disease

Method	Sensitivity (%)
Morphology	1–5
Cytogenetic karyotype analysis	3–5
FISH	1–5
Immunohistochemistry	0.1–5
Consensus primer PCR for gene rearrangements	0.1–1
Flow cytometry	0.01–1
Next-generation sequencing	0.0001–5
PCR and RT-PCR for specific translocations	0.001–0.01
Patient-specific PCR and RT-PCR	0.001

FISH, Fluorescence in situ hybridization; *PCR,* polymerase chain reaction; *RT-PCR,* reverse transcriptase polymerase chain reaction.

Acute Myeloid Leukemia and Myelodysplastic Syndrome

Morphologic Features

Early assessment of the bone marrow is considered the standard measure of response evaluation after induction chemotherapy in patients with AML, although the conventional measure of response after induction chemotherapy is to assess the blast counts on day 28.[26] Early blast clearance indicating adequate cytoreduction confers a good prognosis, irrespective of either the specific day of the bone marrow assessment or evaluation of blast clearance from the peripheral blood. The NCCN guidelines[27] recommend performing bone marrow aspiration and biopsy 14 to 21 days after starting induction therapy (commonly referred to as “day 14 marrow”). Those who have significant residual disease and do not achieve a hypoplastic marrow, defined as cellularity greater than 20% and blasts greater than 5%, are recommended to undergo an early second cycle of induction chemotherapy. Although blast counts on day 14 bone marrow are highly sensitive in predicting remission on day 28, there is increasing evidence of this measurement lacking specificity, as a significant proportion of patients with residual disease on day 14 bone marrow still achieve a complete remission of their disease without a second cycle of induction therapy. This lack of specificity may be explained by an inability of to identify covariates associated with resistance, slow responders in certain AML subtypes, and interobserver and intraobserver variability in assessing blast counts by morphology alone, particularly in the presence of hypoplastic changes induced by therapy.

Remission status is typically assessed from day 28 to 35, as the peripheral blood counts recover from induction chemotherapy. Published guidelines for the morphologic definition of complete remission in patients treated for AML require peripheral blood

neutrophil counts of greater than 1.0×10^9/L, platelet counts of at least 100×10^9/L, less than 5% bone marrow blasts without Auer rods, no extramedullary disease, and independence from red cell transfusion.[27] Patients with MRD at the end of treatment or prior to transplantation have shown similar outcomes as those of patients who have bone marrow blasts >5%.[75] Therefore, more detailed evaluation of bone marrow and peripheral blood samples is needed than is suggested by the remission criteria.

The presence of an increased number of blasts with features similar to the original AML or MDS should be regarded with suspicion. Auer rods (rod-shaped cytoplasmic aggregates of granules) are not a feature of regenerating or nonneoplastic myeloblasts and should be considered evidence of residual disease. Auer rods may rarely be encountered in maturing granulocytes but are nevertheless considered abnormal. Regenerating blasts are usually admixed with promyelocytes and maturing granulocytes, and the presence of sheets of blasts on a smear is a sign of recurrent disease. In contrast, specimens with equal or fewer numbers of blasts compared with promyelocytes usually represent regeneration.[2,76] Clustering of blasts is often difficult to interpret on H&E (hematoxylin and eosin)-stained biopsy specimens, and aggregates of regeneration may be difficult to differentiate from leukemic blasts aggregates. Regeneration usually occurs adjacent to bony trabeculae, and the presence of immature cell aggregates away from the bone is considered abnormal. This abnormal localization of immature cell precursors has been used as a feature of myelodysplasia, but as mentioned, caution should be applied when these criteria are used in patients who have received hematopoietic stem cell transplants.

After transplantation, the normal bone marrow architecture may change, and regenerating immature precursors may be present away from the bone on the biopsy specimens.

Cases previously considered AML with myelodysplasia-related changes and MDS may exhibit multilineage dysplasia before an increase in blasts at relapse. The features of the original multilineage dysplasia should be reviewed, and care should be taken not to overestimate multilineage dysplasia during or immediately after therapy. Dyserythropoietic changes are common during chemotherapy and often include a left shift of erythroid precursors and multinucleation or nuclear irregularity of erythroid cells (**Fig. 56-4**). In addition, some regenerating megakaryocytes can be small and can cluster during or immediately after chemotherapy; however, numerous megakaryocytes with separate nuclear lobes or a predominance and increase of small hypolobated megakaryocytes or micromegakaryocytes with absence of nuclear segmentation can be useful in identifying residual disease. Granulocyte changes after therapy are usually restricted to a left shift without the hypogranulation or nuclear abnormalities commonly seen in association with MDS. Therefore, dysplastic changes of maturing granulocytes are also more reliable in identifying recurrent AML with multilineage dysplasia during or immediately after chemotherapy than erythroid abnormalities alone (**Fig. 56-5**).

Currently, most patients with acute promyelocytic leukemia are treated with both standard chemotherapy and all-trans retinoic acid (ATRA) or combinations of ATRA with arsenic trioxide, and their bone marrow changes are usually similar to those seen in other AML samples. However, ATRA induces maturation of leukemic

blasts/promyelocytes rather than their destruction; thus, morphologic remission can often be achieved without initial significant bone marrow hypoplasia or aplasia.[3,77] The bone marrow in these patients may remain hypercellular, with markedly elevated numbers of promyelocytes (**Fig. 56-6**). These cells usually undergo slow maturation secondary to the therapy, with loss of the t(15;17) cytogenetic abnormality associated with acute promyelocytic leukemia. In this subgroup of patients, it should be understood that the presence of sheets of promyelocytes may not indicate treatment failure, and they should be followed closely with additional bone marrow examinations to confirm that maturational changes are occurring.

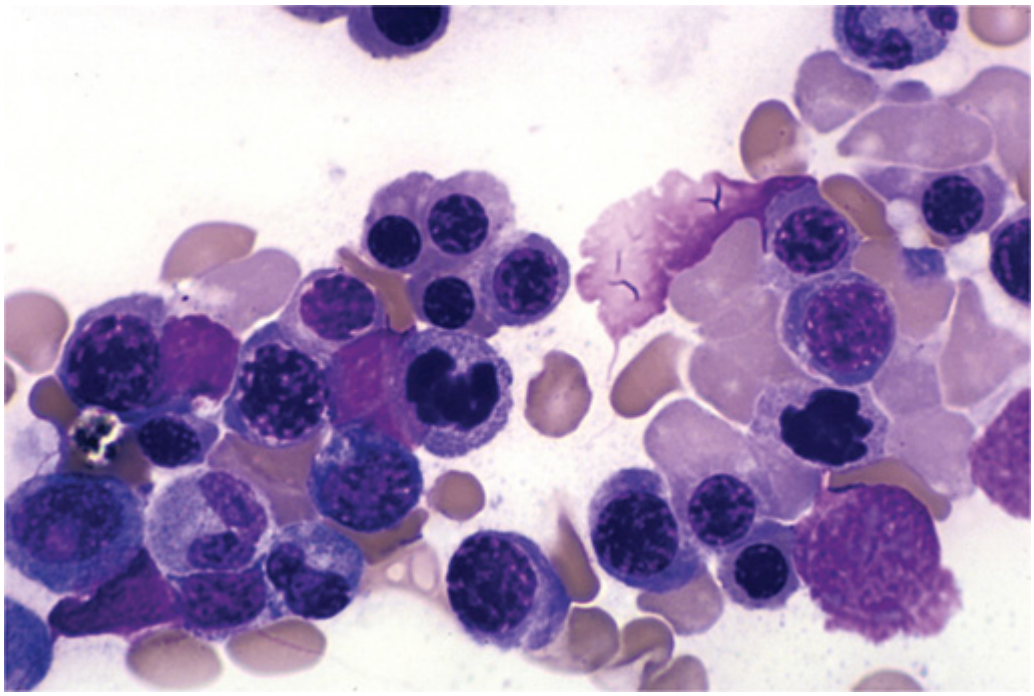

FIGURE 56-4 Post-therapy dyserythropoiesis associated with erythroid hyperplasia are common and should not be interpreted as myelodysplastic syndrome, which should exhibit dysplastic changes of other cell lines.

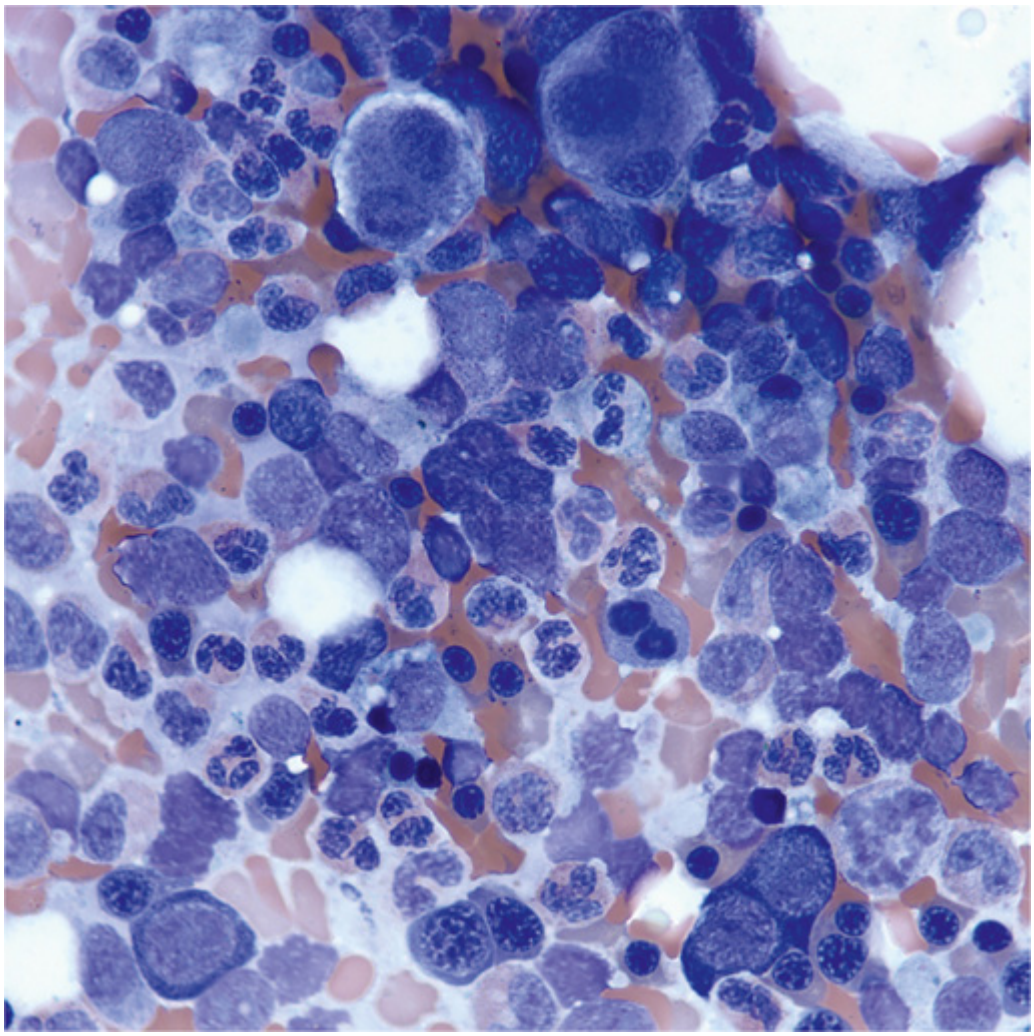

FIGURE 56-5 Relapse in a patient with previous acute myeloid leukemia with myelodysplasia-related changes. Although blasts are only slightly increased, dysplastic changes are clearly present in megakaryocytes, erythroid precursors, and myeloid cells.

Immunophenotyping

Immunophenotyping by multiparametric flow cytometry is an extremely valuable tool in identification of residual disease post-

therapy with proven prognostic significance in evaluating patients with AML post-therapy.[78] Flow cytometry is both more sensitive and more specific for identifying abnormal blast populations than morphology, with some investigators suggesting that the morphologic blast percentage may provide limited data in the setting of high quality multiparametric flow cytometric data.[79] Normal regenerating marrow shows conserved and predictable changes in antigen expression with maturation, but residual blasts show immunophenotypic alterations that deviate from normal patterns, allowing identification as residual disease. Approaches to residual disease detection for AML by flow cytometry include a difference from normal (DfN) approach and the leukemia-associated immunophenotype approach (LAIP). When using both methods (events are collected, if adequate, and an adequate panel is used), abnormal myeloid blast populations can be reliably detected with a sensitivity of 0.1% (1 abnormal cell in 1000), a widely accepted level of clinical significance, and depending on the blast immunophenotype and assay characteristics, can sometimes be detected at lower levels. In the DfN approach, patterns of antigen expression on normal regenerating progenitors are defined using a standardized panel. Using these same panels, abnormal blast populations harbor immunophenotypic alterations that render them "different from normal," allowing their identification as persistent disease. In the LAIP approach, immunophenotypic abnormalities that characterize the leukemic blasts seen at diagnosis are characterized, and subsequent samples from the patient are evaluated for these same alterations. The abnormalities that characterize abnormal blasts in myeloid neoplasms can include

abnormal intensity of antigen expression (i.e., increased or decreased expression; absence of an antigen; or homogeneous expression of an antigen normally expressed in a heterogenous fashion); asynchronous antigen expression (co-expression of a mature and immature antigen); and expression of an antigen of a lymphoid lineage.[80] Examples of MRD evaluation for AML by flow cytometry are shown in **Figure 56-7**. Both the DfN and LAIP approaches are associated with strengths and weaknesses, and the best approach involves incorporating both strategies in an evaluation for MRD. A combined approach is endorsed by the European Leukemia Net (ELN). The reader is referred to published comprehensive guidelines from the ELN for assessing MRD in AML.[81] Although flow cytometric MRD is applicable in the vast majority of cases, it should be noted that sensitivity may be lower with some immunophenotypes (i.e., acute promyelocytic leukemia), which may benefit from alternative methods of MRD detection, including molecular-based studies. The ELN guidelines present a scheme for assessing AML MRD based on the genetic and immunophenotypic features of the acute leukemia at diagnosis.

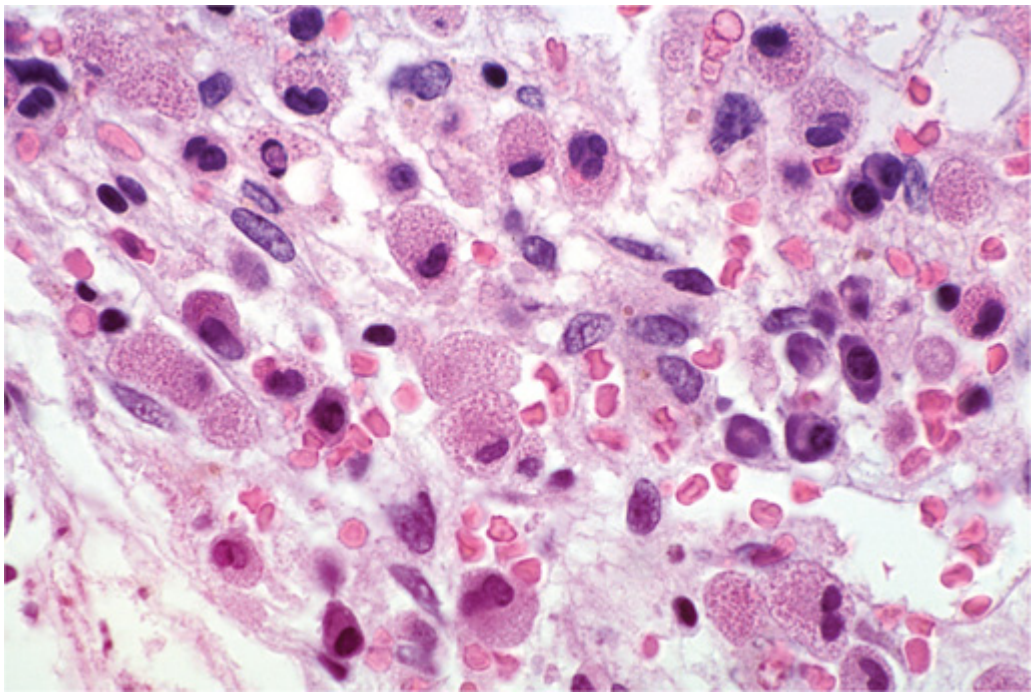

FIGURE 56-6 Residual promyelocytes during therapy for acute promyelocytic leukemia treated with all-trans retinoic acid. Follow-up bone marrow examination showed continued maturation of granulocytes without a change in therapy.

Paraffin section immunohistochemistry may be of value in selected cases, particularly in the presence of left-shifted cell aggregates on H&E-stained sections. Immunophenotyping can show that the immature cell aggregates of regeneration represent a spectrum of left-shifted cells that are not exclusively blast cells, whereas in residual/recurrent leukemia, blast cell aggregates are a more uniform population of neoplastic cells. The identification of cohesive clusters of cells expressing the immature cell antigen CD34 and/or an aberrant combination of antigens may favor residual or recurrent disease. Immunohistochemistry has also been described as useful for

identifying residual disease in cases of AML with an *NPM1* mutation, as immunohistochemistry for NPM1 may assist in identifying clusters of residual neoplastic cells.[82]

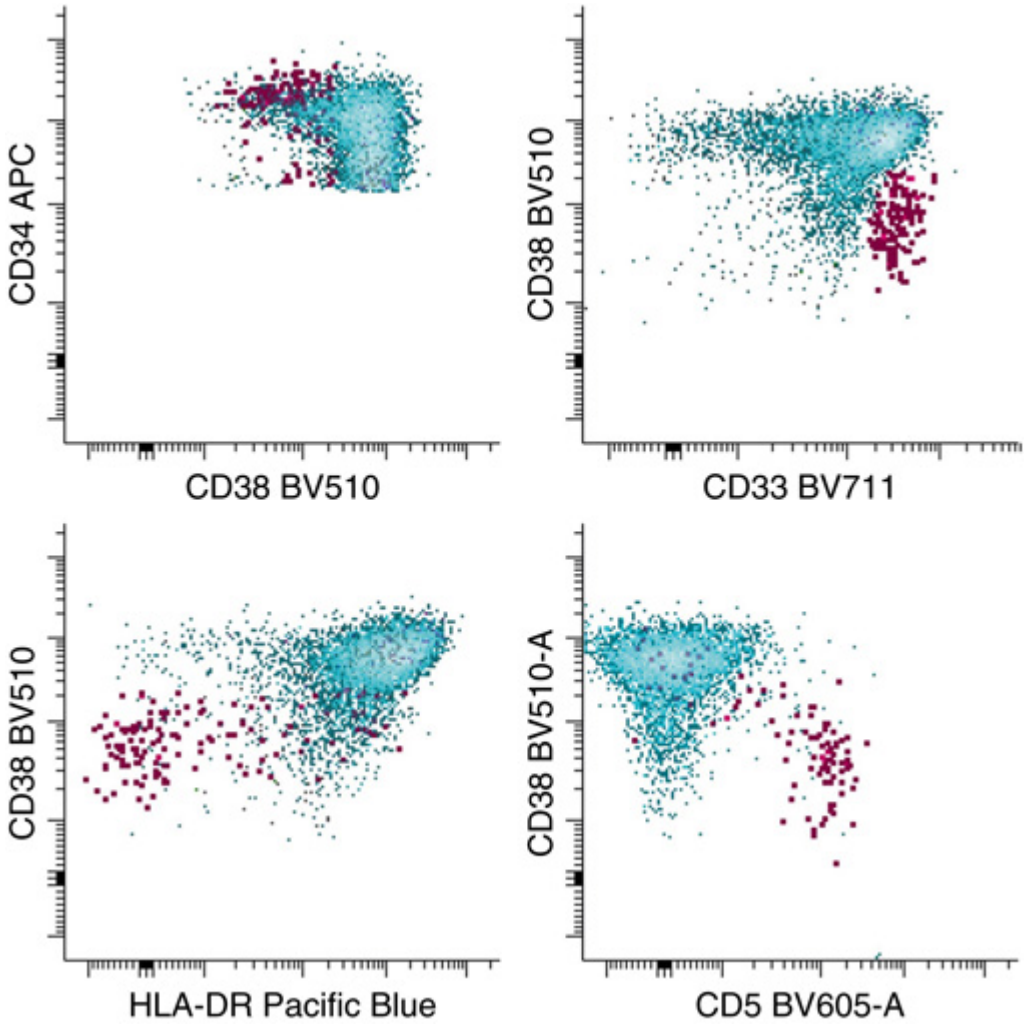

FIGURE 56-7 Example of minimal/measurable residual disease (MRD) in acute myeloid leukemia. All plots show CD34-positive myeloid blasts (1.2% of the total white blood cell count). Normal regenerating blasts are *colored aqua* (1.0% of the white blood cells), and residual leukemic blasts are *highlighted in red* (0.2% of the white blood cells). The residual leukemic blasts in this case have a stem-cell–like immunophenotype with bright CD34 and dim CD38 and show aberrant

expression of CD5, CD33 (increased), CD38 (decreased), and HLA-DR (decreased to absent). Although the residual leukemic cells are difficult to distinguish from normal progenitors on the plot of CD34 versus CD38, the leukemic and normal blasts are well separated using other antigens and a multiparametric approach with evaluation of several informative projections allows confident identification of the abnormal population.

Cytogenetics and Molecular Studies

Cytogenetic studies are not performed on all post-therapy samples but may be of value in some situations. Although some cases of AML are associated with normal karyotypes, most show a clonal cytogenetic abnormality. However, an abnormal karyotype in the diagnostic bone marrow is an independent prognostic indicator that is predictive of induction success, cumulative incidence of relapse, and OS in adult patients with AML.[83-88] Identification of that abnormality in a follow-up sample is highly supportive of relapsed disease. Karyotype analysis routinely includes the study of 20 cells; therefore, this method is not optimal for the detection of MRD when blast cells are below 5%. Most cytogenetic laboratories also perform FISH, which allows the screening of several hundred cells for a specific abnormality. This method may increase the detection rate of residual disease over karyotype analysis alone, but it requires knowledge of the karyotypic abnormality of the original disease and probes specific for that abnormality. FISH probes are useful in

identifying monosomies, trisomies, and masked 11q23.3 abnormalities, in addition to balanced chromosomal translocations. The detection of numerical chromosomal abnormalities by FISH during clinical remission has been shown to correlate with an increased risk of disease recurrence.[89] Another use of karyotype analysis and FISH is evaluation for XX/XY chimerism.[90] If a patient receives an allogeneic transplant from a donor of the opposite sex, karyotype and FISH studies can reveal the presence of residual host cells in the bone marrow, even if they are of a normal karyotype. In addition, human leukocyte antigen (HLA)-based chimerism studies are used in a similar fashion.[91] However, the detection of nondonor cells in the marrow is less predictive of recurrent disease than is the detection of a leukemia-specific abnormality.

The frequent presence of mutations in AML allows molecular monitoring of MRD. These methods generally use PCR and can potentially detect 1 tumor cell in 100,000 cells. Efforts have been made to standardize these procedures,[92] but there are still some differences in methodology and preferred targets of study among laboratories. In general, PCR testing for MRD requires knowledge of the original karyotypic or other molecular abnormalities and primers and probes for those abnormalities. However, not all markers are equally suitable for MRD monitoring. Currently, *RUNX1*::*RUNX1T1* of t(8;21)(q22;q22.3), *PML*::*RARA* of t(15;17)(q24.1;q21.2), *CBFB*::*MYH11* of inv(16)(p13.1q22)-t(16;16)(p13.1q22), and *NPM1* mutations are thought to be the best molecular markers for MRD tracking.[81] The persistent presence of these molecular alterations after therapy is a strong predictor of relapse. These mutations can be determined accurately by real-time qPCR using cDNA as a template

(**Fig. 56-8**). The assays for detecting these mutations are highly sensitive (10^{-4} to 10^{-6}) with excellent reproducibility, provided the sample is of good quality and the assay was carefully performed with appropriate controls. In addition, because of the unique translocations and insertions (in the case of *NPM1*), the assays for measuring these mutations are extremely specific with minimal background. This approach is applicable in about 40% to 50% of patients with AML harboring one of these mutations. The ELN has recommended molecular assessment of MRD in these groups of patients at clinically informative time points. These include at diagnosis, 2 months after standard induction/consolidation therapy, at the end of treatment, during follow-up, and every 3 months for 24 months after the end of treatment. The prognostic cutoff of MRD measurements differ among these groups of patients with AML harboring one of these mutations. Specifically, for AML with *CBFB*::*MYH11,* MRD of ≥10 fusion copies per 10^5 *ABL* (control gene) copies at follow-up or end of therapy is associated with increased relapse risk but no difference in OS.[93] In AML with *RUNX1*::*RUNXT1,* MRD of ≥100 fusion copies per 10^5 *ABL1* copies during follow-up is associated with a negative prognostic effect on relapse, but MRD negativity at earlier time points is prognostically irrelevant.[93,94] On the other hand, a >3 log reduction in levels of *RUNX1*::*RUNXT1* fusion transcripts between the diagnosis and end of induction/consolidation therapy has a favorable prognostic effect with respect to relapse rate and OS.[94] It should be noted that low stable levels of *CBFB*::*MYH11* and *RUNX1*::*RUNX1T1* fusion transcripts may be detected by PCR years after the initial diagnosis without any evidence of disease relapse, suggesting other genetic or

epigenetic aberrations are necessary for these types of leukemia to develop in addition to the translocations.[95] Thus, low levels of these fusion transcripts may not necessarily signify relapse, and consideration of the actual levels and dynamics of their abundance may be warranted. In APL, undetectable *PML*::*RARA* by sensitive PCR (at least 10^{-3}) at the end of consolation therapy is the most important MRD end point, associated with low risk of relapsed and better OS.[96,97] The presence of detectable *NPM1* mutation after 2 cycles of cytotoxic therapy or at the end of therapy is associated with high risk of relapse.[98-100]

The qPCR approach described herein cannot be used for MRD assessment in the other AMLs without the aforementioned translocations or mutations. Molecular MRD must be determined using the other known mutations identified at the time of diagnosis based on the NGS approach. However, this approach may not be readily applicable because of two obstacles. First, the sensitivity of the current routine target sequencing platforms is ~1% to 5%, which is relatively low compared with that of the qPCR approach. In some cases, this level of sensitivity may not even be reached, depending on the library preparation protocol and bioinformatics pipeline. Second, many recurrently mutated genes found in AML are not suitable for use as molecular markers to track MRD. Some of the mutated genes, most commonly *DNMT3A, TET2,* and *ASXL1* (so called "*DTA* genes"), persist at variable allele frequencies post-therapy despite achievement of complete morphologic remission (CR).[101-103] These mutations most likely represent postremission clonal hematopoiesis (CH) instead of residual AML and are present in the preleukemic founder clones. Postremission CH can persist long-term post-

therapy and as a group is not correlated with increased relapse rate.[104] However, the persistence of non-*DTA* mutations during CR post-therapy (above a cutoff variant allele frequency [VAF] of 2.5%) has a negative prognostic effect with respect to the rates of relapse, relapse-free survival, and OS.[101-103] These findings support the utility of somatic mutations in non-preleukemic (non-*DTA*) genes as molecular MRD markers in AML. However, because of the tendency of these mutations to fluctuate as a result of clonal evolution, which results in gains or losses of these mutations at relapse, it is recommended that mutations in *FLT3*-ITD, *FLT3*-TKD*, NRAS, KRAS, DNMT3A, ASXL1, IDH1, IDH2,* and *MLL*-PTD not be used as single markers in MRD assessment. However, combination of two or more of these markers may be useful in determining MRD. For "hot-spot" mutations, for example, in codon 132 of *IDH1;* codons 140 and 172 of *IDH2;* and codons 12, 13, and 61 of *KRAS,* droplet digital PCR (ddPCR) can be used to detect mutation at a sensitivity lower than that achieved by conventional target sequencing platforms. However, this approach is not feasible for the detection of other mutations that occur less frequently, as specific primers and probes need to be designed for individual patients. The detection of multiple mutations in different patients may be facilitated by the development of error-corrected NGS using unique molecular identifiers that enhance detection sensitivity and, in some cases, identify as few as 1 mutated cell in 1 million cells.[105,106]

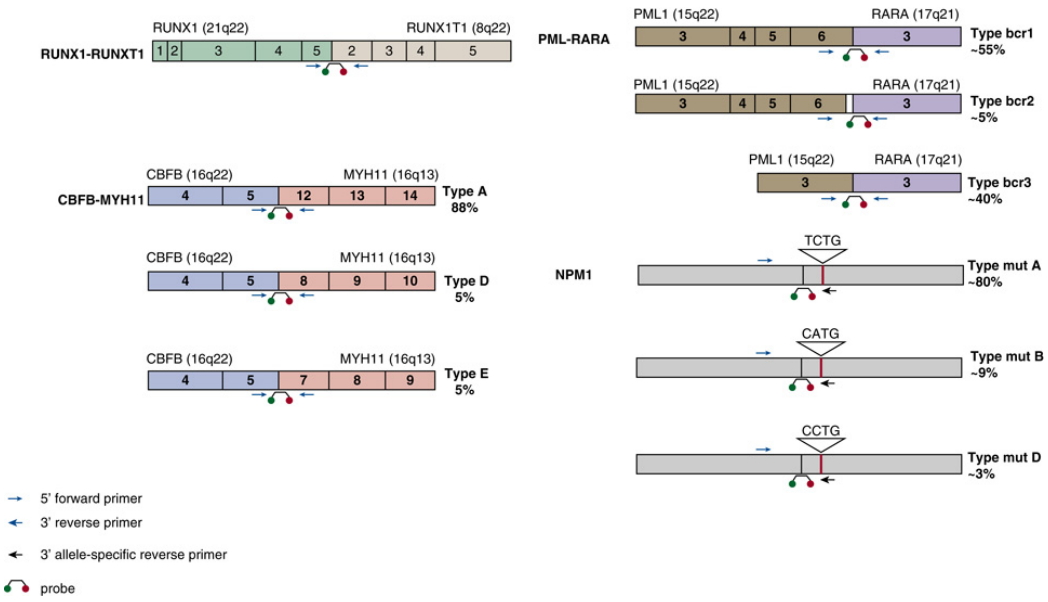

FIGURE 56-8 Real time quantitative polymerase chain reaction (PCR) measurement of four recommended biomarkers to measure minimal residual acute myeloid leukemia. The breakpoints of the reciprocal translocations and the types of insertions in *NPM1* mutations are indicated along with their respective frequencies: the forward primers, reverse primers (mutant-specific, if applicable), and probes are marked.

In general, MRD assessment using these molecular markers requires periodic assessment of peripheral blood and bone marrow (e.g., every 3 months) for at least 2 years after the end of treatment. As discussed, the prognostic effect of MRD varies depending on its levels and the disease in question. Patients with complete molecular remission or molecular persistence at low levels below specific cutoffs may have a low risk of relapse. On the other hand, molecular

progression, defined as an MRD increase of 1 log or more between any two positive samples, or molecular relapse, defined as an MRD increase of 1 log or more between any two positive samples in a patient with previously complete molecular remission, may signify increased risk of relapse. In summary, there is clear evidence that MRD is an independent prognostic indicator in AML that is important for risk stratification and treatment planning in conjunction with other well-established parameters and has the potential to serve as a surrogate end point for survival in clinical trials to facilitate drug approval.[81]

Acute Lymphoblastic Leukemia

Morphologic Features

Because of the morphologic overlap with myeloblasts, many of the features useful in distinguishing leukemic myeloblasts from regenerating myeloblasts also apply to lymphoblasts. Comparison to the original leukemic blasts is useful to identify distinctive features, such as variation in blast cell size and cytoplasm, cytoplasmic vacuoles, nucleoli, and nuclear convolutions. Some lymphoblasts may contain cytoplasmic granules, but Auer rods are not seen. Distinguishing lymphoblasts from normal hematogones may create diagnostic difficulties and is discussed in detail herein. Not surprisingly, the early clearance of blast cells from peripheral blood (by day 7) and bone marrow (by day 14 or 15) in acute lymphoblastic leukemia (ALL) is associated with an improved prognosis in both adults and children.[107]

Bone marrow biopsy morphology can also help detect residual leukemia in ALL. As with leukemic myeloblasts, residual or recurrent

lymphoblasts tend to cluster and form aggregates on biopsy material.

As noted, one of the most challenging problems in the evaluation of post-therapy ALL specimens is distinguishing residual or recurrent disease from hematogones. Hematogones are more frequent in children and may be the predominant cell type in bone marrow aspirates in some cases, such as in children with idiopathic thrombocytopenic purpura. They may also occur in children with other cytopenias, malignancies at other sites, or regenerating bone marrow after treatment for leukemia.[108-110] These cells also occur in adults, particularly after hematopoietic cell transplantation, but they may be seen in adults with lymphoma, autoimmune diseases, or acquired immunodeficiency syndrome.[111,112] Because of their monotonous lymphoid appearance and precursor B-cell lineage, they are easily misinterpreted as leukemic cells. Hematogones are predominantly small cells with scant cytoplasm, with smaller numbers of admixed large cells (**Fig. 56-9**). The small cells are uniform in size with round to oval nuclei but exhibit a spectrum of other nuclear features, ranging from homogeneous, bland chromatin without nucleoli to mature, clumped chromatin. These cells differ from most lymphoblasts, which are usually larger and have more cytoplasm, more variation in size, irregular nuclear contours, distinct nucleoli, and no evidence of maturation. Although hematogones may be numerous in aspirate material, they are usually inconspicuous in biopsy material. Hematogones are usually found as interstitial infiltrates, whereas leukemic blasts often form aggregates in bone marrow biopsy specimens. Immunophenotyping provides a reliable method for distinguish hematogones from neoplastic blasts.

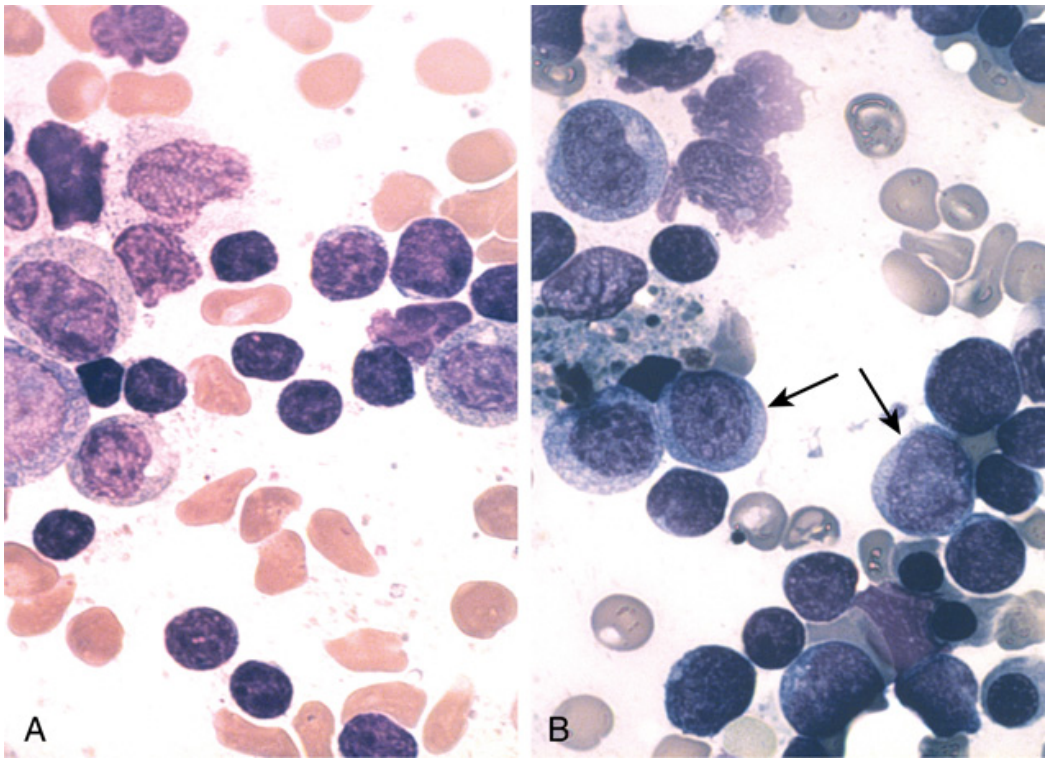

FIGURE 56-9 Hematogones after therapy.A, There is an increase in precursor cells, which are generally small and uniform in size and lack nucleoli. **B,** This similar population of cells also has larger blast cells *(arrows)* with nucleoli, in a specimen from an 8-month-old treated for *KMT2A*-rearranged pro–B-cell acute lymphoblastic leukemia. This sample shows an immunoglobulin kappa gene rearrangement by polymerase chain reaction analysis and a small population of *KMT2A*-rearranged cells by fluorescence in situ hybridization, consistent with minimal residual disease.

Immunophenotyping

Flow cytometry has been applied for MRD detection in B-lymphoblastic leukemia/lymphoma (B ALL) for many years and is considered standard of care for patients after therapy. The prognostic significance of flow cytometry for MRD detection has been described in numerous studies (summarized in a meta-analysis conducted by Berry and colleagues[113]) with some multivariate analyses suggesting MRD has the highest predictive value among prognostic inidcators.[114] Flow cytometry using an adequate panel and with collection of sufficient events can reliably be performed with a sensitivity allowing detection of an abnormal population at 0.01% (1 in 10,000 cells). Similar to AML MRD, detection of residual disease in B-ALL relies on identifying abnormal blast populations by virtue of the immunophenotypic aberrancies these abnormal cells harbor. Similar to myeloid maturation, B-lymphoid maturation takes place in the marrow; therefore, distinguishing abnormal blasts from normal background hematogones is critical.[115,116] This is particularly true because hematogone hyperplasia may be seen in the setting of marrow regeneration post-therapy or posttransplant, particularly in pediatric populations. An example of MRD detection by flow cytometry in the setting of B-ALL is illustrated in **Figure 56-10**.

Similar to AML, the abnormalities seen in B-ALL may include abnormal intensity of an antigen (for instance, CD9, CD10, CD34, and CD58 are often aberrantly overexpressed, and CD38 and CD45 are often underexpressed on abnormal blasts) or expression of an antigen of a different lineage (with expression of CD13 and CD33 being relatively common). Although not required, in some cases, knowledge of the diagnostic immunophenotype can be particularly

helpful in confirming that a presumed abnormal population represents abnormal blasts.

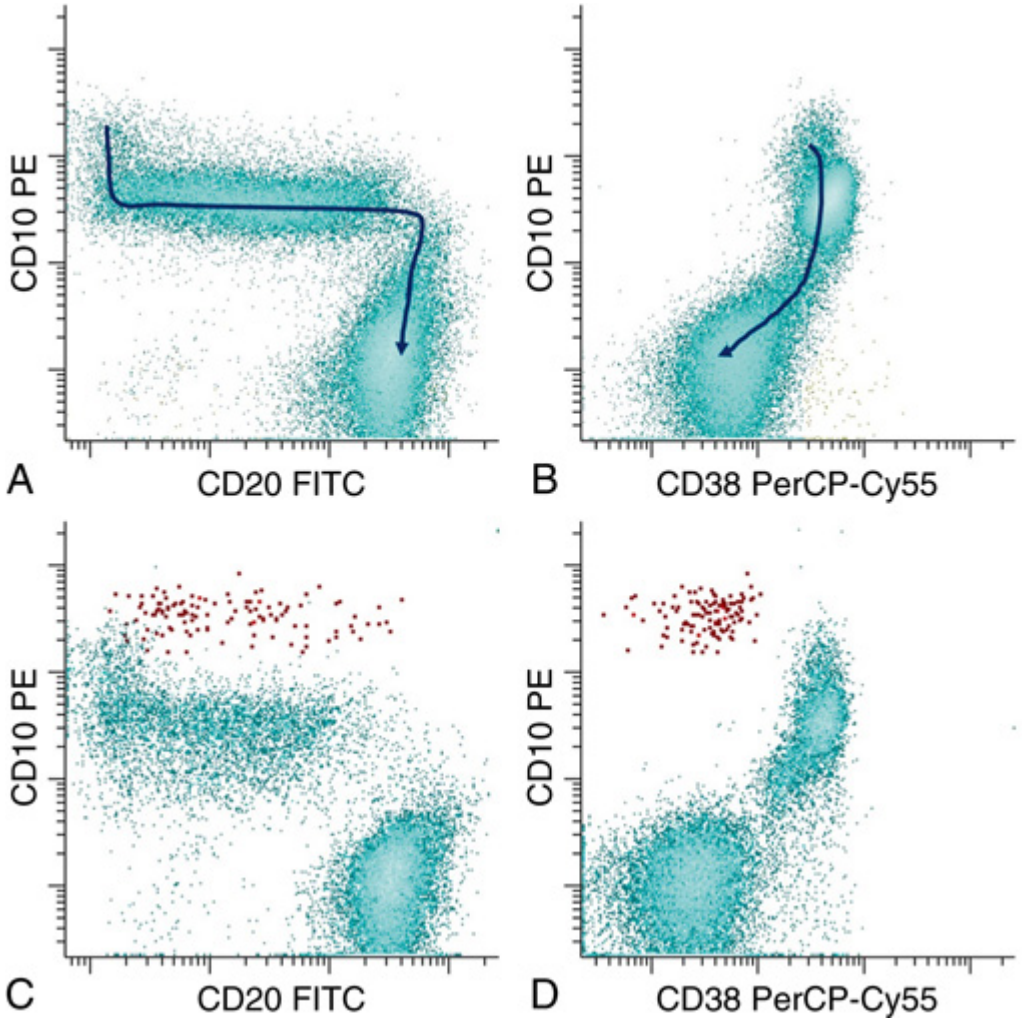

FIGURE 56-10 Example of minimal/measurable residual disease (MRD) in B-lymphoblastic leukemia. All plots show CD19-positive B cells. **A** and **B** plots demonstrate normal B-cell maturation with the *arrows* illustrating changes in antigen expression with B-cell maturation. Normal early hematogones have bright CD10 and express CD38 without CD20 and with dim CD45. With maturation, CD10 and CD38 decrease in intensity, and CD20 and CD45 increase. Normal

hematogones may be increased post-therapy, particularly in children, but retain normal patterns of antigen expression. **C** and **D** plots illustrate CD19 positive B cells from a patient post-therapy for B-lymphoblastic leukemia with residual leukemic cells present. Normal background B cells and precursors are *colored aqua* and predominate; persistent leukemic cells account for 0.03% of the nucleated mononuclear cells and are *highlighted in red*. The leukemic cells can be differentiated from normal mature B cells and hematogones by aberrant expression of bright CD10 with variable CD20 and without CD38.

A number of targeted immunotherapies are used in the setting of B-ALL, in particular in refractory/recurrent disease. Targeted therapies in common use include agents targeting CD19, including T cells genetically engineered to express a chimeric antigen receptor (CAR T cells) directed against CD19 and bispecific small molecules with specificity for CD3 and CD19 designed to engage the host T-cells against tumor CD19-positive B cells. Monoclonal antibodies directed against CD20 and CD22 are also in common use for treatment of B-ALL. The targets of such therapeutic agents may overlap with the antigens used for population identification or characterization, complicating immunophenotypic analysis. In the setting of targeted therapies, the immunophenotype of normal populations may be altered, and neoplastic blasts may become antigen negative or change lineage, a phenomenon that has been described in the setting

of T-cell engaging anti-CD19 therapies.[117,118] Awareness of targeted therapies in use is critical for correct interpretation of data, and in some cases, alternative gating strategies (**Fig. 56-11**) may be required.[119]

As T-cell maturation takes place in the thymus, immature T cells should not be identified in the bone marrow, and the detection of cytoplasmic CD3-positive and TdT-positive populations are suggestive of residual T-lymphoblastic leukemia/lymphoma (T-ALL). Different flow cytometric approaches and panels for T-ALL MRD detection have been described in the literature.[116,120]

Immunohistochemical studies are also useful in the evaluation of immature cell aggregates in the bone marrow of patients treated for ALL. Though regenerating hematogones are typically present in an interstitial pattern, leukemic lymphoblasts tend to form clusters in the bone marrow, and the detection of clusters of TdT-positive and/or CD34-positive cells on biopsy material may be suggestive of residual disease (**Fig. 56-12**).[121]

Cytogenetics and Molecular Studies

Karyotype and FISH analyses offer results similar to those described for AML. Karyotype abnormalities are often detected at presentation with ALL, but a significant number of patients have normal karyotypes or abnormalities that are not easily followed by molecular methods. The specific abnormalities most often followed in patients with ALL are *BCR*::*ABL1* of t(9;22)(q34.1;q11.2), *TCF3*::*PBX1* of t(1;19)(q23.3;p13.3), *ETV6*::*RUNX1* of t(12;21)(p13.2;q22.1), and *KMT2A* translocations, particularly t(4;11).[122,123] PCR testing directed to a specific balanced cytogenetic translocation is very

sensitive and can detect abnormal cells at a level of 1 translocated cell in 100,000 cells. Therefore, specific PCR testing against balanced translocations is the easiest and most sensitive method for identifying molecular genetic evidence of residual disease.[124] ALL cells also demonstrate T-cell and B-cell receptor gene rearrangements.[125] Such rearrangements are not entirely lineage-specific (dual immunoglobulin heavy chain [IGH] and T-cell receptor chain rearrangements are common in precursor B-cell ALL), but they can be used for residual disease testing. The European BIOMED-2 group has developed a series of PCR primers that are accurate and now widely used for establishing and monitoring B-cell and T-cell receptor gene rearrangements.[126] The sensitivity of the BIOMED-2 primer and PCR assay is about 1 mutated cell in 100 cells. This sensitivity is too low for detection of MRD; thus, regular BIOMED-2 PCR assay is not suitable for molecular detection of MRD. For many years, allele-specific oligonucleotide PCR (ASO-PCR) has been the gold standard to molecularly monitor residual disease in B-ALL and other B-cell neoplasms.[127] It requires the demonstration of a B-cell or T-cell immunoglobulin gene rearrangement in the pretreatment diagnostic acute leukemia sample. The junctional region of the rearrangement is then sequenced, and PCR primers and probes are designed specifically for the individual patient's abnormality. The follow-up samples are then tested with the patient-specific primers and probes for residual disease. This test can be performed in a quantitative manner.[128,129] This methodology is capable of detecting residual disease at a high sensitivity of 0.001% and is useful for predicting relapse in childhood ALL.[127,130,131] However, the technique is complex and labor-intensive, requiring extensive

knowledge and experience, as the junctional regions of each leukemia have to be identified before the patient-specific real-time qPCR assays can be designed for MRD monitoring.

NGS is now the emerging modality used to detect MRD in lymphoid neoplasms, particularly in B-ALL. Briefly, the assay takes advantage of the unique *VDJ* gene rearrangement occurring on the genomic locus of the IgH gene in individual B-lymphoid cells (including B-lymphoid tumor cells) to track tumor loads by combining PCR and NGS-based deep sequencing technologies[132,133] (**Fig. 56-13**). The sensitivity of this assay is extremely high, reaching 1 in a million cells, provided adequate DNA input. The different modalities for MRD assessment in B-ALL are summarized in **Table 56-2**.

MRD determined by molecular means is an excellent prognostic tool to assess risk stratification in B-ALL. Studies of B-ALL patients demonstrate that molecular MRD is a powerful predictor for relapse and clinical outcome.[114,134-137] In adults with relapsed/refractory B-ALL, MRD negativity after salvage therapy is associated with significantly longer OS.[138]

In addition to prognostic significance, PCR-based MRD is playing an increasingly important role in tailoring individual risk-directed treatment decisions in B-ALL. A clinical trial of 778 pediatric patients with B-ALL showed that therapy intensification and reduction based on MRD levels significantly improved overall clinical outcome. Moreover, intensive chemotherapy or stem cell transplantation protocols of high risk patients designed on PCR and MRD-based readouts led to a fivefold increase (16%–78%) in the 5-year event-free survival (EFS) rate.[139] A study with 278 tested adult

patients with B-ALL demonstrated that poor early MRD response, in contrast to conventional ALL risk factors, is an excellent tool to identify patients who may benefit from allogeneic stem cell transplantation in the context of intensified adult ALL therapy.[140] Among adult patients with B-ALL in complete hematologic remission with MRD $\geq 10^{-3}$ treated with blinatumomab, 78% achieved a complete MRD response after one cycle, and complete MRD response after blinatumomab treatment in this population was associated with significantly improved OS and relapse-free survival compared with that of MRD nonresponders.[141]

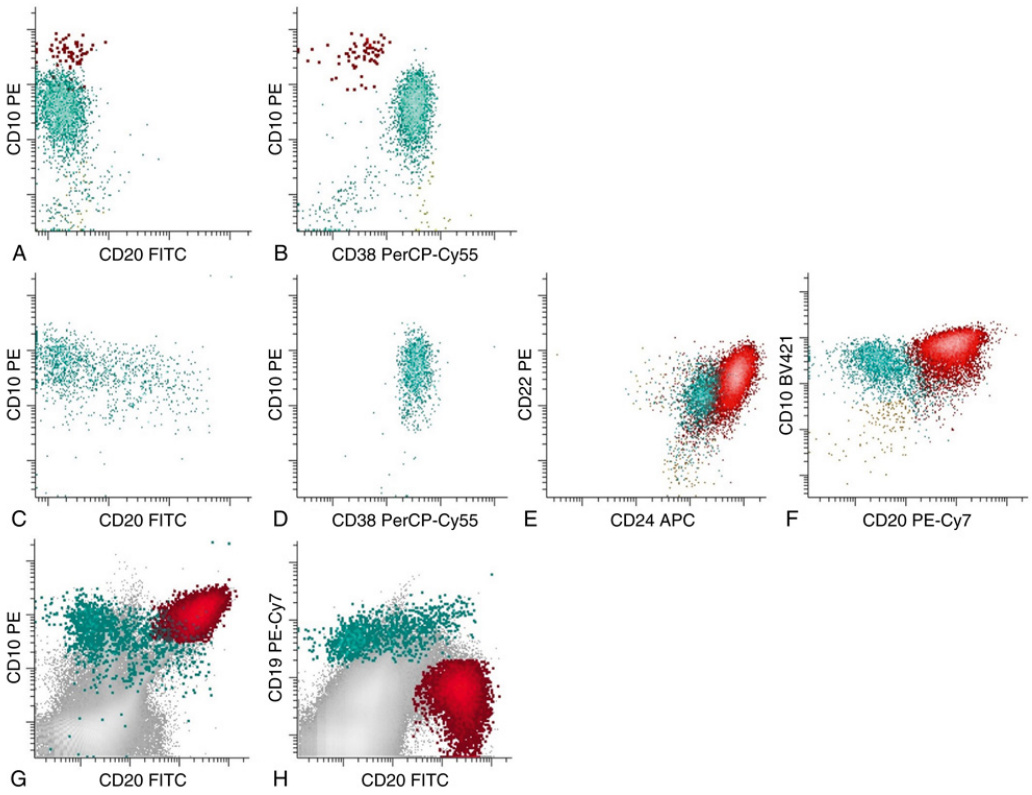

FIGURE 56-11 Effect of targeted therapy on flow cytometric studies.A and **B,** These plots show CD19-positive B cells from a patient with a history of B-lymphoblastic leukemia who has received a regimen including anti-CD20 therapy. This sample shows two distinct immature B-cell populations. Normal residual hematogones are *shown in aqua* and lack expression of CD20 as a result of prior anti-CD20 therapy. In addition, a small population of leukemic blasts is *highlighted in red* (0.02% of the nucleated mononuclear cells) and shows aberrant bright CD10 with dim to absent CD38. **C–H,** These dot plots show flow cytometric data from a patient with B-lymphoblastic leukemia

who received an anti-CD19 targeted T-cell engaging therapy. **(C)** and **(D)** show CD19-positive B cells, which have left-shifted B-cell maturation with a predominance of early hematogones but with no immunophenotypic abnormalities. When using CD19 to identify B cells, no abnormal population is evident. In the setting of anti-CD19 therapy, it is critical that CD19 not be the only method used for identification of abnormal cells. **(E)** and **(F)** show B cells from this same sample expressing both CD22 and CD24. Using this alternative gating strategy, B cells include two subsets: a normal hematogone subset *(aqua)* and a population of leukemic blasts *(red)*, which accounts for 0.9% of the nucleated mononuclear cells. The abnormal blasts show bright expression of CD20 and CD24, co-expressed with CD10. **(G)** and **(H)** show all mononuclear cells. When looking at all mononuclear cells, the abnormal population *(highlighted in red)* is evident. The residual leukemic cells have lost CD19 expression post-therapy and can be distinguished from normal background hematogones, which retain CD19 expression *(highlighted in aqua)*.

Chronic Myeloid Leukemia

Chronic MPNs have overlapping morphologic features and are generally diagnosed by a combination of morphologic, clinical, and genetic findings (see **Chapter 47**). Chronic myeloid leukemia (CML) is the most common chronic MPN and the one that most often requires post-therapy evaluation. A variety of therapies have historically been used for CML, including bone marrow transplantation and interferon-α therapy, but TKI therapy is now standard.

Morphologic Features

With treatment of the chronic phase of CML, the bone marrow becomes less cellular; with some therapies, it may become normocellular or even slightly hypocellular. The myeloid-to-erythroid (M/E) ratio, which is usually markedly elevated before treatment, usually returns to normal or may become decreased. In these cases, it is often difficult to determine by morphologic features alone whether leukemic cells persist in the bone marrow. The most common clues to residual disease are hypercellularity, the presence of clusters of atypical "dwarf" megakaryocytes, prominent basophilia,[142] and in some cases, the continued presence of clusters of Gaucher-like histiocytes.[143,144] Despite these clues, cytogenetic or molecular genetic studies to detect *BCR*::*ABL1* t(9;22)(q34.1;q11.2) are needed to definitively identify the continued presence of leukemia.

In the past, busulfan, hydroxyurea, and interferon-α therapies were used to treat CML, with some variation in the degree of bone marrow response. Some patients achieved clinical features of remission, with improvement in peripheral blood counts.[145,146] With

busulfan, the bone marrow usually remains hypercellular, with an elevated M/E ratio. Megakaryocytes tend to be increased with therapy, and this increase is associated with an increase in bone marrow fibrosis. With hydroxyurea, the marrow cellularity decreases somewhat but usually remains above normal, with only a moderate correction in the M/E ratio. The number of megakaryocytes and degree of marrow fibrosis, however, tend to decrease with hydroxyurea. With interferon-α, complete normalization of peripheral blood counts may occur. The bone marrow remains slightly hypercellular in most patients, but approximately one-quarter of patients have normal bone marrow features on interferon-α.[146] Marrow megakaryocytes remain elevated, with associated fibrosis; bone marrow macrophages are reportedly increased in the marrow. Despite the improvement in marrow cellularity, most patients continue to show cytogenetic evidence of clonal bone marrow disease.

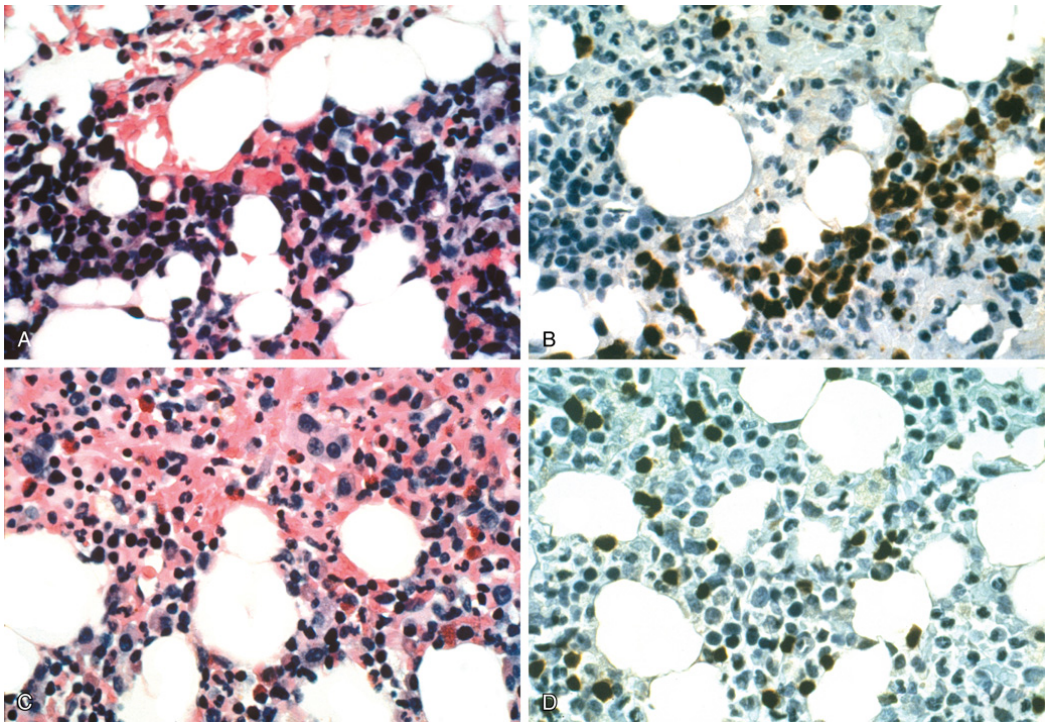

FIGURE 56-12 Immunohistochemical features of residual precursor B-cell acute lymphoblastic leukemia and normal precursor B cells (hematogones).A and **B,** This case of residual leukemia shows aggregates of terminal deoxynucleotidyl transferase (TdT)-positive cells. **C** and **D,** In this case, there is an increase in hematogones, which do not form distinct aggregates on the biopsy material, and only scattered individual TdT-positive cells.

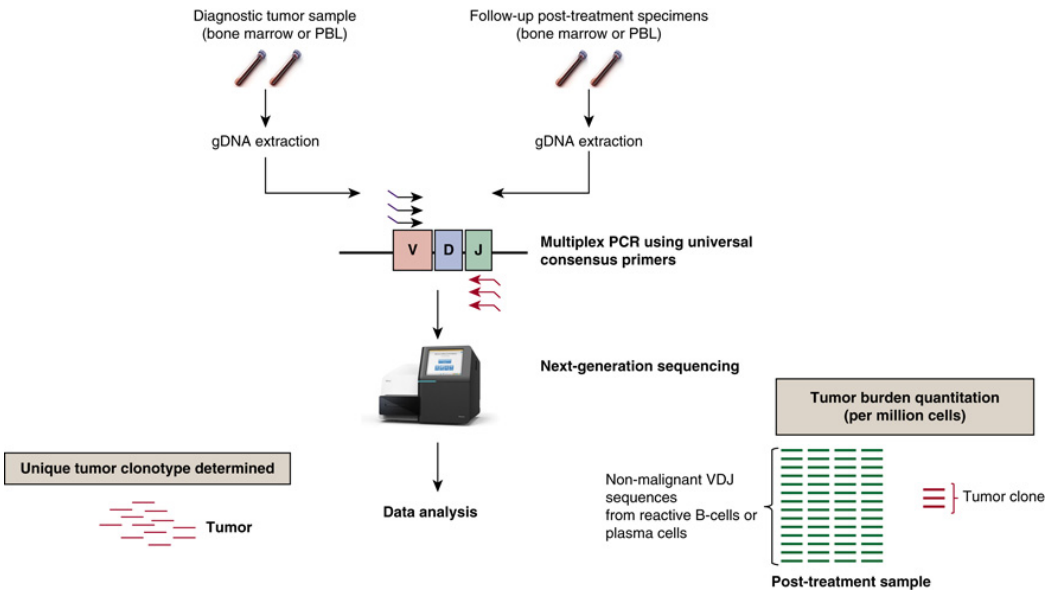

FIGURE 56-13 Detection of minimal residual disease in B-cell neoplasms using deep sequencing of immunoglobulin heavy chain (IGH) genes. Briefly, genomic DNA extracted from tumor or post-treatment specimens are subjected to library preparation using multiplex primers. These libraries are then sequenced by next-generation sequencing (NGS). The tumor-specific VDJs are identified. The tumor burden is measured by the percentage of tumor-specific reads in a pool of VDJ reads.

Table 56-2

ALL, Acute lymphoblastic leukemia; *IGH,* immunoglobulin heavy chain; *MFC,* multiparametric flow cytometry; *NGS,* next-generation sequencing; *PCR,* polymerase chain reaction; *qPCR,* quantitative PCR.

Bone marrow transplantation was the standard treatment for CML in the past and is still considered the only totally curative therapy.[147] After transplantation, the bone marrow undergoes the expected changes of aplasia, followed by regeneration. The majority of patients with CML treated with transplantation are cured and show normocellular or hypocellular bone marrow without specific abnormalities. Relapse specimens from patients treated with transplantation show changes similar to de novo disease, with granulocytic hyperplasia, basophilia, and hypercellularity, and are usually not diagnostic dilemmas.

At the time of this writing, most patients with all phases of CML are treated with a TKI that directly blocks the effects of the *BCR*::*ABL1* fusion gene.[148] The TKI most commonly used is imatinib, although newer-generation *BCR*::*ABL1* inhibitors (dasatinib, nilotinib) are available for patients who fail to respond, relapse, or experience intolerance to imatinib. Imatinib therapy results in a clinical, morphologic, and at least partial or complete cytogenetic remission in most patients, with a reduction in marrow cellularity, normalization of the M/E ratio, and normalization of megakaryocyte number and morphology.[149-151] The peripheral blood is the first to respond to imatinib therapy; the white blood cell count returns to normal, basophils decrease, and the platelet count normalizes, with normal-appearing platelets occurring after about 2 months of therapy. The hemoglobin level tends to decrease slightly during therapy. A subset of patients may have neutropenia or thrombocytopenia while receiving the drug. The bone marrow hypercellularity gradually decreases, and by 8 to 11 months, the marrow is normocellular or hypocellular, with a normal or decreased

M/E ratio in most patients. Even in the chronic phase, bone marrow blast cells and megakaryocytes decrease, the number of hypolobated megakaryocytes decreases, and megakaryocyte clustering becomes less common as the marrow cellularity decreases (**Fig. 56-14**). This therapy can also gradually eliminate the marrow fibrosis that is prominent is some cases of CML,[149,151,152] although progression of myelofibrosis has also been reported, mostly in cases with acceleration or blast phase.[150] Patients with accelerated or blast-phase CML, however, also show rapid decreases in peripheral blood and bone marrow blast cell counts.[149] After long-term treatment with imatinib, some patients may have increased pseudo-Gaucher cells and reactive lymphoid nodules.[150]

Relapse of CML may take the form of chronic or blast-phase disease and may result from natural evolution of the disease with cytogenetic evolution, from loss of responsiveness to imatinib therapy through the acquisition of mutations within the kinase domain of *BCR*::*ABL1* or amplification of the fusion gene, or through other mechanisms that are not yet clearly understood. Occasionally, patients have a myelodysplastic or blastic process in cells that are negative for the Philadelphia (Ph) chromosome.[153] If the patient had a previous blast phase, comparison to the original material may be useful, similar to the evaluation of post-therapy acute leukemia specimens. Morphologic evaluation is of limited utility in predicting the type of blast crisis in CML, and immunophenotyping studies are required for accurate classification of the blast cell lineage.[154]

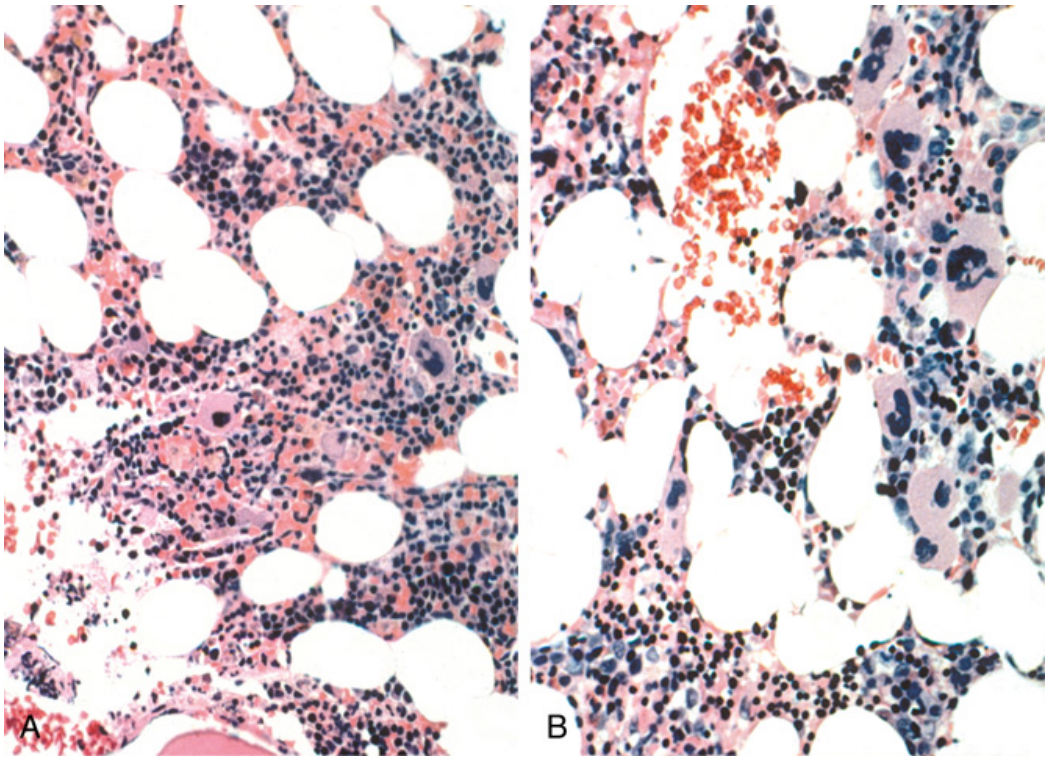

FIGURE 56-14 Post-therapy changes in chronic myeloid leukemia. After tyrosine kinase inhibitor (TKI) therapy, samples may be morphologically normal **(A)** or show residual clusters of atypical megakaryocytes **(B)**. Both samples remained positive for *BCR*::*ABL1* by reverse transcriptase polymerase chain reaction (RT-PCR).

Immunophenotyping

Immunophenotyping studies generally are not useful in the follow-up of patients treated for CML in chronic phase. If an increase in blasts is noted during the course of therapy, flow cytometry can be used to determine the lineage of the blast population. Flow cytometry can be used in the follow-up of patients treated for CML in

accelerated phase (with increased blasts) or in patients treated with induction for blast phase of CML. In this setting, the approach for identifying abnormal myeloid or lymphoid blasts is similar to that described for MRD assessment in acute leukemias.

Cytogenetics and Molecular Studies

The majority of patients treated with busulfan, hydroxyurea, and interferon-α have karyotypic evidence of disease during and after treatment. However, approximately 13% of patients treated with interferon-α, 63% or more of patients treated with imatinib for 60 months or longer, and most patients treated with hematopoietic cell transplantation have no karyotypic evidence of disease.[142,155,156] More sophisticated ultrasensitive methods, however, reveal the continued presence of very low levels of the Ph chromosome in the stem cells of patients treated with imatinib.[156] Many other patients receiving these therapies have partial cytogenetic responses.[148] The reversion to normal bone marrow morphology does not correlate with loss of t(9;22) in all cases, and molecular or cytogenetic confirmation is needed. Patients treated with imatinib may develop a cytogenetic remission after only 2 months of therapy, but the time to achieve a cytogenetic response is variable. Patients who have early normalization of bone marrow cellularity by 2 to 5 months are reportedly more likely to have a complete cytogenetic response.

Various guidelines have been suggested for monitoring patients on therapy, particularly those receiving imatinib.[157-160] Most recommend routine karyotyping and real-time quantitative reverse transcriptase (RT)-PCR to measure *BCR*::*ABL1* transcripts be performed at regular intervals. FISH studies are generally not

recommended for long-term follow-up, mainly because most FISH assays have background levels of up to 6%, limiting the ability to detect very low levels of disease. However, a highly sensitive interphase double-fusion assay, sometimes termed D-FISH, can detect very low levels of *BCR*::*ABL1* fusion and is much more sensitive than conventional karyotype analysis, although it does not allow the detection of additional chromosomal abnormalities.[161,162]

Measurement of *BCR*::*ABL1* transcript levels using real-time qPCR standardized to the international reporting scale (IS) is now the principal recommended monitoring strategy.[163] The introduction of the IS has allowed harmonization of testing processes, standardization of the nomenclature for reporting molecular response, and the development of reference material.[164-168] The incorporation of this molecular monitoring in the management of CML was initially recommended in 2013 by the ELN and is essential in monitoring patients receiving imatinib or other TKIs. Based on many clinical studies over the years, an optimal response was recommended by the ELN (2020) as follows: *BCR*::*ABL1* 10%, ≤1%, and ≤0.1% at 3, 6, and 12 months of TKI therapy, respectively.[163] A major molecular response (MMR), defined as ≤0.1% *BCR*::*ABL1* measured on the IS, is predictive of negligible risk for disease progression over 12 months[169,170] and is now considered a primary outcome measure in CML clinical trials. In addition, treatment of CML with TKIs has enabled many patients to achieve very low or undetectable levels of disease; some of these patients remain in sustained remission when treatment is withdrawn. Thus, accurate definition of deep molecular responses is increasingly important for optimal patient management and risk stratification.[164] A deep

molecular response (DMR, *BCR*::*ABL1* ≤0.01% IS) represents an important second milestone, as achievement of a sustained DMR is a prerequisite for a trial of drug discontinuation with the aim of achieving treatment-free remission (TFR). Molecular response (MR)4, defined as ≤0.01% on the IS scale, maintained for at least 1 year is associated with stable DMR in CML, after which no MMR loss occurs if the patients are fully compliant and remain on a standard TKI dose.[171] MR4.5, defined as ≤0.0032% on the IS scale, is a new molecular predictor of superior long-term outcome. No patients who have achieved MR4.5 experienced progression of the disease.[172] In addition, a sustained MR4.5 prior to treatment discontinuation may be associated with a higher rate of TFR than with MR4.[173] It can be reached by a majority of patients treated with imatinib, although it takes, on average, 3 years longer to achieve MR4.5 than with MR4. However, the duration to achieve MR4.5 can be shortened with optimized high-dose imatinib. Achieving MMR or MR4 after 3 years of imatinib may be predictive of the likelihood of reaching MR4.5 at a later time point upon continuation of TKI therapy. Patients on imatinib for 3 years who have achieved MR4 have a higher probability of achieving MR4.5 with continued imatinib. On the other hand, patients without MMR at 3 years of imatinib therapy have a negligible probability of achieving MR4 or MR4.5 with up to 5 additional years of imatinib. Similarly, patients with MMR but not MR4 at 3 years of imatinib therapy have a significantly lower cumulative incidence of MR4.5 than that of patients with MR4.[163] These latter two groups of patients may benefit from a more potent TKI if achievement of MR4.5 is the ultimate goal. Thus, accurate and precise measurements of *BCR*::*ABL1* on the IS scale is critical to

assess and correctly stratify molecular responses for patient prognosis and management (**Fig. 56-15**).

After transplantation, patients frequently remain *BCR*::*ABL1* positive by PCR for several months, with no clinical evidence of relapse in long-term clinical follow-up.[174] In part, the cause of these presumably false-positive PCR results is the presence of the fusion product in terminally differentiated cells, such as Gaucher-like histiocytes.[175] With time, these cells disappear, and the PCR test becomes negative. Therefore, PCR testing in the months immediately after transplantation may not have clinical relevance. Use of serial qPCR methods may be one means of avoiding overinterpretation of a positive PCR result, with an interval increase in the amount of *BCR*::*ABL1* transcripts presumably indicating residual or recurrent disease.[156] Performing qPCR tests 12 months and longer after transplantation is useful in predicting relapse.[176]

BCR::*ABL1*-Negative Myeloproliferative Neoplasms

BCR::*ABL1*–negative MPNs such as essential thrombocythemia (ET), primary myelofibrosis (PMF), and polycythemia vera (PV) may require post-therapy evaluation. Therapies for these MPNs are diverse and vary depending on disease stage. For instance, during the chronic phase of PV, phlebotomy is frequent, whereas patients with ET frequently take aspirin prophylactically and may also receive anagrelide. Hydroxyurea is a common cytoreductive therapy used in all MPNs, and some patients may receive interferon-α. Newer targeted therapies, such as JAK2 inhibitors (ruxolitinib), may be used in patients with *JAK2* mutations, and some patients may

undergo hematopoietic cell transplantation, particularly those with PMF. Each therapy confers specific changes to the bone marrow, which manifest morphologically and, in some cases, immunophenotypically; in others, the changes to the bone marrow affect cytogenetic and molecular data as well.

Morphologic Features

After therapy, each MPN may show different morphologic features. During the chronic phase of PV, patients are frequently treated with phlebotomy, which leads to a physiologic, responsive additional increase in marrow cellularity. Cytoreductive therapies such as hydroxyurea or busulfan result in decreased bone marrow cellularity across all three MPNs, though these chemotherapeutic agents do not significantly reduce marrow fibrosis.[177] Both interferon and busulfan reduce megakaryocyte numbers, whereas hydroxyurea may increase them. In some cases of ET, anagrelide is used to decrease platelet counts; common changes in megakaryopoiesis can be seen with increased numbers of immature small forms as a result of inhibition of both megakaryocyte maturation and endoreduplication.[178]

JAK pathway inhibitors (ruxolitinib) have been developed and are used to treat some patients with MPN with *JAK2* V617F mutations. Though significant morphologic marrow changes at 6 months or 1 year are generally not seen,[179,180] some patients with longer-term therapy (>2 years) have shown decreased bone marrow fibrosis and normalization of marrow cellularity with decreased megakaryocyte clustering.[181,182]

Finally, bone marrow transplantation may be performed in patients with MPN and, in particular, is more frequent in patients

with PMF. After transplantation, if successful, marrow cellularity may return to normal with reestablishment of M/E ratios and slow resolution of fibrosis over the course of 3 months to more than 1 year.[183,184]

Immunophenotyping

In general, immunophenotyping has limited value in monitoring residual disease in *BCR*::*ABL1*-negative MPNs if the blast percentage is normal. A clear exception is the monitoring of blasts in MPNs with disease acceleration or when blast transformation has occurred. In these cases, blasts are most frequently of myeloid origin, though rare cases of ALL have been reported; however, unlike myeloid blast transformation, it is unclear whether these cases of ALL are clonally related to the underlying MPN.[185-187]

Cytogenetics and Molecular Studies

The majority of *BCR*::*ABL1*-negative MPNs have a normal karyotype, and cytogenetic abnormalities are detected in only a subset. When disease persists, these cytogenetic abnormalities generally persist.[188] In cases of ET and PV, though cytogenetic abnormalities are rare (~5% of patients), abnormalities of chromosomes 1, 8, 9, and 20 are the most frequently observed.[188-191] In PMF, abnormalities are more frequent (30%–40% of patients) and are seen in chromosomes 1, 8, 9, 13, and 20.[192] Again, these cytogenetic abnormalities can be followed during therapy with routine G-banding karyotype analysis. One caveat to be aware of in cytogenetic analyses is that marrow aspirate specimens in patients with fibrotic marrow may be hemodiluted and nonrepresentative of bone marrow constituents. In

addition, during blast transformation, cytogenetic abnormalities may evolve, and in a subset, a complex karyotype may develop.[184,192] FISH studies, as in AML, can also be used to assess for more common cytogenetic abnormalities such as monosomies, trisomies, or translocations. These methods have inherent detection limits, as discussed previously. As in other transplant patients, HLA-based chimerism studies may be useful to assess for residual host marrow in patients with bone marrow transplants.

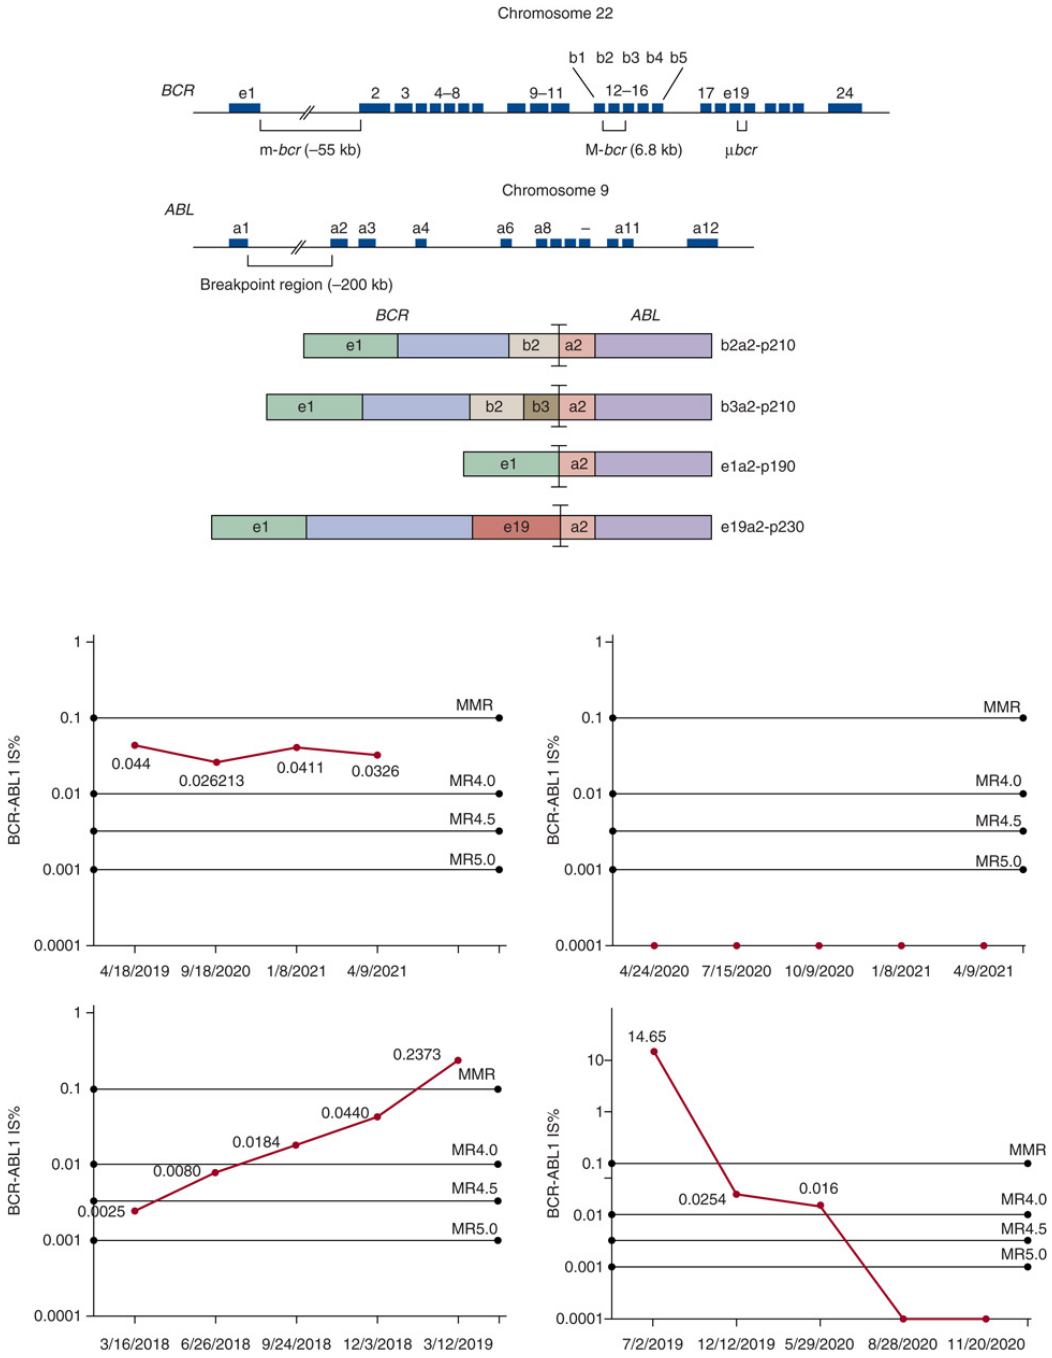

FIGURE 56-15 Examples of different patterns of molecular responses in patients with chronic myeloid leukemia (CML) treated with tyrosine kinase inhibitors (TKIs). The different breakpoints of

BCR::*ABL1* and the primers and probes used for measurement of fusion transcripts are indicated. Persistent major molecular response (<0.1% international reporting scale ([IS]), *upper left*; persistent deep molecular response, *upper right*; molecular relapse, *lower left*; molecular remission achieved after TKI therapy, *lower right*.

Molecular studies are routinely used in MPNs, as most patients with PV, ET, and PMF show a *JAK2* V617F mutation with general frequencies of greater than 95%, 50% to 60%, and 50% to 60%, respectively.[157,192-195] More recently, novel insertion and deletion mutations in calreticulin *(CALR)* exon 9 have been identified in patients with *JAK2*-negative ET and PMF (>30% of these patients).[196-198] In addition, a small subset of patients with ET and PMF has mutations in exon 10 of *MPL* (5%–10% of patients).[199,200] The presence of acquired mutations within the *JAK2, CALR,* and *MPL* driver genes in the majority of patients with MPNs permits use of these mutations as quantitative markers of MRD for additional evaluation of response to therapeutic intervention.[201] The reduction of *JAK2* V617F varies according to the treatment modalities used. Though hydroxyurea can result in partial reduction of at least 30% in *JAK2* V617F in about half of patients early in the disease course, prolonged treatment does not seem to cause further reduction in allele burden.[202-206] The majority of patients with PV and ET who are maintained on interferon therapy may experience sustained reduction in *JAK2* V617F and even complete MR in a few selected cases.[207-209] Busulfan, though less frequently used because of its

leukemogenic potential, can induce substantial MRs, including complete molecular remission, in a subset of patients.[210] Though JAK2 inhibitors can be effective in improving clinical symptoms and prolonging OS, they have only modest effect in lowering the *JAK2* V617F mutation burden.[179,211] However, there is data suggesting long-term therapy may result in partial or complete MR in a small subset of patients.[212] Allogeneic stem cell transplantation (ASCT) is the only curative option for patients with advanced disease. MPN MRD assessment of *JAK2* V617F mutation by sensitive quantitative methods is a useful outcome and relapse predictor in ASCT, allowing preemptive intervention before overt relapse.[213-215] Similarly, interferon significantly reduced *CALR* exon 9 mutation burden in patients with *CALR*-mutated ET, with some achieving complete MR.[216] qPCR of *MPL* W515L and W515A mutations in individual patients has demonstrated clearance of MRD in patients with PMF after ASCT.[217,218] Although *MPL* exon 10 mutations are amenable to allele-specific qPCR approaches, their low frequency in ET and PMF, compared with that of *JAK2* V617F and *CALR* exon 9 mutations, has limited their wide clinical use as MRD markers.

A variety of allelic-specific qPCR approaches are available for quantitating *JAK2*. These tests have different performance characteristics, but all assays appear to have a sensitivity of ~0.1% to 0.5%.[219-222] About 2% to 5% of PV cases do not harbor *JAK2* V617F but do have exon 12 mutations in *JAK2*. Sensitive real-time qPCR has also been successfully designed for some common exon 12 mutations.[223] *MPL* exon 10 hot spot and other mutations can also be detected by qPCR, but because of their low frequency in MPNs, their clinical utility as MRD markers has not been well established.

Fragment length analysis (FLA) followed by capillary electrophoresis has been widely adopted for *CALR* exon 9 mutation detection. It displays a sensitivity compatible for MRD monitoring (approximately 1%) but remains semiquantitative.[224-226] The qPCR approach cannot detect the entire spectrum of *CALR* mutations, but it can be used to detect quantitatively and with higher sensitivity the most common *CALR* type 1 (52 bp deletion) and type 2 (5 bp insertion) mutations, which account for ~80% of *CALR* mutations.[227] Though earlier assays have analytical sensitivities of ~1% to 2%, the most sensitive qPCR assay was reported to reach a sensitivity of <0.1% for type 1 mutations and <0.01% for type 2 mutations.[228] ddPCR has also emerged as a useful technique for molecular MRD assessment in MPN. For *JAK2* V617F quantitation, ddPCR correlates well with qPCR, even for allele burden as low as 0.1%.[229-231] For *CALR* type 1 and type 2 mutations, ddPCR has a sensitivity of 0.025% and is capable of detecting MRD after ASCT and earlier detection of increasing MRD levels prior to clinical relapse.[232,233]

Chronic Lymphoproliferative and Plasma Cell Disorders

Morphologic Features

Many lymphoproliferative disorders involve the bone marrow focally, forming aggregates of neoplastic cells. Because of the focal nature of the disease, it may be missed on a review of aspirate smears alone, and bone marrow trephine and clot sections are essential for a complete evaluation. Bilateral bone marrow biopsies increase the yield of detected focal lesions.[158] However, positron emission

tomography with computed tomography (PET-CT) has largely replaced staging bone marrow biopsies for Hodgkin lymphoma and diffuse large B-cell lymphoma.[234] The finding of focal aggregates of atypical large lymphoid cells usually presents no diagnostic dilemma, but aggregates of small lymphoid cells of residual lymphoma must be distinguished from reactive lymphoid aggregates, which are common in older adults.[235,236] Even when the patient has a history of large cell lymphoma, discordant lymphoma morphology may occur, with only low-grade lymphoma present in the bone marrow aggregates.[237,238]

Reactive lymphoid aggregates are usually composed of predominantly small lymphocytes with admixed large cells; they may contain histiocytes and plasma cells as well. These aggregates are usually small and well circumscribed and may contain intervening small vessels. The reactive aggregates are nonparatrabecular in location.[236] The pattern of neoplastic aggregates of residual or recurrent lymphoma in the bone marrow varies by lymphoma type.[239,240] Follicular lymphoma characteristically involves the marrow in a paratrabecular pattern, with associated fibrosis and no fat spaces present between the lymphoid aggregate and the bone. After therapy, these aggregates may be less cellular, but they continue to exhibit lymphoid cells and fibrosis adjacent to bone.[241] In some cases, only T cells remain after therapy, and immunophenotyping by immunohistochemical studies and/or flow cytometry are necessary to determine whether aggregates contain neoplastic cells in this setting. The presence of any remaining B cells in the paratrabecular aggregates and/or an abnormal B-cell population by concurrent flow cytometry, however, is supportive of

residual bone marrow involvement. Mantle cell lymphoma may show a mixed paratrabecular and nonparatrabecular pattern. An interstitial pattern of disease predominates in hairy cell leukemia and in some cases of chronic lymphocytic leukemia. Most other lymphomas show a predominantly nonparatrabecular pattern. Splenic marginal zone lymphoma may show an intrasinusoidal pattern of disease,[242,243] but this pattern does not appear to be specific for this disease, and patients who have undergone splenectomy for splenic marginal zone lymphoma may have nodular bone marrow involvement.[244] The most helpful morphologic clues for identifying bone marrow involvement by lymphoma are a paratrabecular pattern of involvement, the presence of a monotonous cell population within the aggregates, and large, irregularly shaped aggregates that show infiltration into the surrounding normal hematopoietic marrow. Small nonparatrabecular lymphoid aggregates in patients with a history of lymphoma usually require ancillary immunohistologic studies to determine the nature of the aggregates.[238,245]

Plasma cells can have a variety of atypical features in multiple myeloma, including binucleation or multinucleation, prominent nucleoli, and abnormally condensed chromatin. However, these can also be seen in reactive plasma cells. Standard response criteria for multiple myeloma incorporate both bone marrow findings and results of testing for paraproteins in the peripheral blood and serum. A complete response requires <5% plasma cells in bone marrow aspirates, absence of paraprotein by immunofixation of serum and urine, and lack of soft tissue plasmacytomas.[246] Detecting persistent

or recurrent disease often requires ancillary testing (immunophenotyping and/or molecular methods).

Immunophenotyping

Immunophenotyping is the most common method of detecting residual disease in the bone marrow of patients with a history of lymphoma and can be performed by flow cytometry and/or immunohistochemistry. Immunohistochemistry allows the benefit of evaluating cells in the context of architecture, and flow cytometry allows for a multiparametric approach and, in most cases, a greater level of sensitivity. Sampling differences between bone marrow aspirate and biopsy material (particularly when abnormal cells are associated with fibrosis) may decrease the yield of flow cytometry. In such cases, flow cytometry can be performed on a disaggregated core biopsy.

When a suspicious lymphoid aggregate is present on the biopsy, immunohistochemical methods are useful. Because most lymphomas are of B-cell lineage and most bone marrow lymphocytes are T cells, the detection of aggregates or sheets of B cells in lymphoid aggregates is often good evidence of involvement by lymphoma (**Fig. 56-16**).[236,240] The primary exception to the correlation between an increase in aggregate B cells and lymphoma is when reactive germinal centers are present in the marrow. Bone marrow germinal centers are most common in patients with autoimmune diseases,[247] and these types of aggregates should not automatically be considered evidence of bone marrow involvement by lymphoma. Bone marrow evaluation can usually be accomplished with a relatively small panel of antibodies, including CD3 and CD20 (or PAX5 or CD79a if the

patient has received anti-CD20 therapy), but more antibodies can be used if subclassification is needed. Aberrant expression of CD5 or CD43 in B cells is common in many lymphomas of small B cells in the marrow, and this finding is also useful to confirm bone marrow involvement by disease.[248]

Paraffin section immunophenotyping may cause confusion in cases of bone marrow involvement by follicular lymphoma. Follicular lymphoma at almost any site is usually accompanied by a relatively large number of T cells, and T cells may predominate in marrow involved by this type of lymphoma. Although CD10 expression is commonly seen with follicular lymphoma, this antigen is often lost in bone marrow lymphoma aggregates, and such antigen expression may be seen in non-neoplastic lymphocytes. Detection of BCL6 protein by immunohistochemistry may be useful in detecting follicular lymphoma, but this antigen is not restricted to germinal-center cells. For this reason, the morphologic feature of paratrabecular aggregates is considered the most reliable means of detecting follicular lymphoma in the marrow.[245] Cyclin D1 may be helpful in detecting persistent mantle cell lymphoma. LEF1 is positive in chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), but it is also positive in T cells and should only be interpreted in the context of T-cell and B-cell markers.

Antibodies directed against annexin A1 can been used to determine whether CD20-positive cells represent persistent/recurrent hairy cell leukemia; however, annexin A1 is positive in myeloid-lineage cells and may be difficult to interpret when small numbers of cells are present in a regenerating bone marrow. Antibodies specific to the *BRAF* V600E mutation have been

developed that can be used to identify MRD with high specificity and sensitivity.[249,250]

For plasma cell disorders, CD138 can be used to quantitate plasma cells, and aberrant expression of cyclin D1, CD31, CD56, and CD117 on neoplastic plasma cells can be detected by immunohistochemistry.[251-253] Kappa and lambda staining also plays a role, as stringent complete response requires the lack of detectable paraprotein and <5% plasma cells on aspirate smears, plus a normal serum-free light chain ratio and absence of monotypic plasma cells in the bone marrow biopsy by immunohistochemistry.[246] However, widespread adoption of MRD testing, either by flow cytometry or molecular methods, may supplant these standard response criteria.

Flow cytometry is a useful modality to identify abnormal lymphoid cells or plasma cells in follow-up of post-therapy samples for lymphoid neoplasms and plasma cell neoplasms, respectively. In the setting of B-cell neoplasms, the utility of flow cytometry for residual disease detection has been established for a number of disease entities, including CLL/SLL[254,255] and hairy cell leukemia,[256] among others. Among mature lymphoid neoplasms, the data is perhaps strongest in CLL/SLL, where consensus guidelines exist and MRD has been established as a significant prognostic factor.[255,257] It should be noted, though, that the value of MRD data may vary based on therapeutic regimen.[254] In the setting of plasma cell neoplasms, post-therapy samples may be followed by flow cytometry and/or immunohistochemistry. Flow cytometry often underestimates plasma cell numbers because of factors such as hemodilution and preservation of plasma cells; therefore, immunohistochemistry for a plasma cell marker such as CD138 is helpful in accurately

enumerating plasma cells. That being said, flow cytometry is effective in identifying abnormal plasma cell populations with high sensitivity and in distinguishing normal and abnormal plasma cells. As with other neoplasms, the potential effect of targeted therapies on the immunophenotype of both normal cells and neoplastic plasma cells must be taken into consideration when interpreting flow cytometric data for residual myeloma in the post-therapy setting. **Figure 56-17** illustrates MRD detection by flow cytometry for plasma cell neoplasms. Several consensus guidelines exist for defining MRD by flow cytometry and for using this information for clinical decision making.[257-259] The prognostic value of MRD in plasma cell myeloma (PCM) is well established.[246,260,261] In fact, in one study, multiparametric flow cytometric detection of monotypic plasma cells on day 100 was the most relevant independent prognostic factor in PFS and OS among patients with myeloma undergoing autologous cell transplantation.[262]

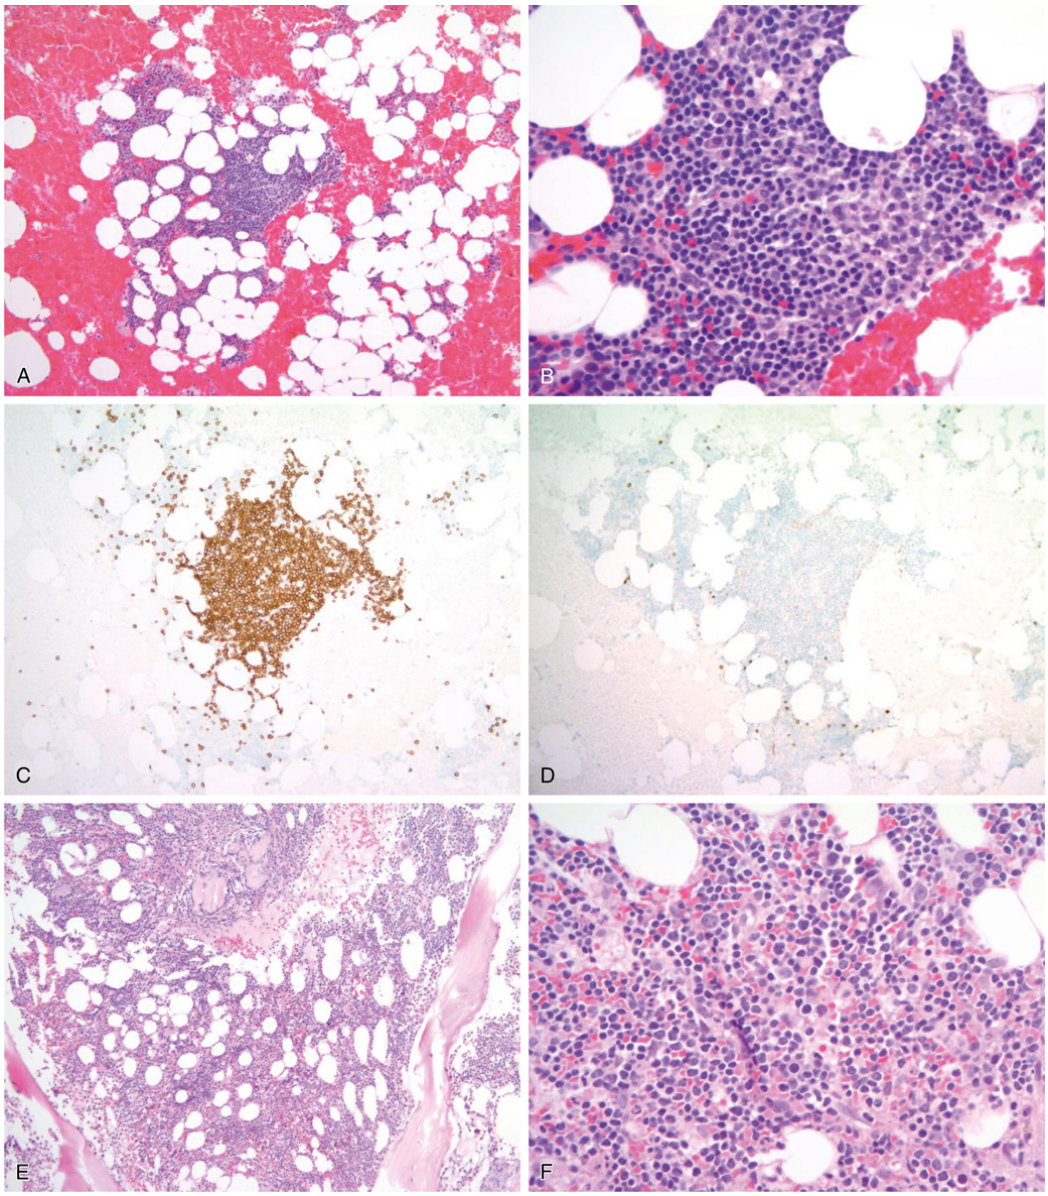

FIGURE 56-16 Morphologic and immunohistochemical features of reactive and neoplastic lymphoid aggregates. This reactive lymphoid aggregate in a patient treated for mantle cell lymphoma (**A** and **B**) is small, well circumscribed, and composed of CD3-positive T cells **(C)** with essentially no B cells detected by PAX5 staining **(D)**. Cyclin D1 was also negative.

In contrast, a recurrent mantle cell lymphoma shows diffuse marrow infiltration by small and intermediate-sized lymphoma cells (**E** and **F**), which are positive for cyclin D1.

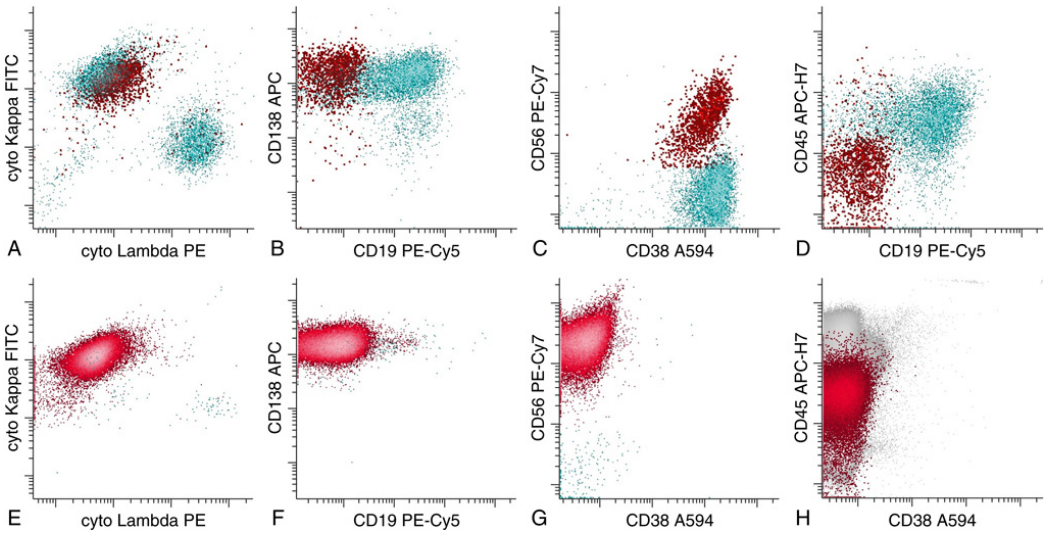

FIGURE 56-17 Example of residual disease post-therapy in a plasma cell neoplasm.A–D, All dot plots show plasma cells (cells expressing CD38 or CD138) in a bone marrow specimen from a patient with a history of plasma cell myeloma who presents for a pre-transplant evaluation. Plasma cells account for 0.8% of the white blood cells and include a minor subset of abnormal plasma cells *(highlighted in red)*, which account for 0.2% of the white blood cells, and a subset of normal background plasma cells *(colored aqua)*. The abnormal plasma cells have cytoplasmic kappa light chain expression, aberrantly express CD56, and lack CD19 and CD45; the normal plasma cells show polytypic cytoplasmic light chain expression and express normal levels of CD19 and CD45. Plots **E–G** show plasma cells (cells expressing CD38 or CD138) in a bone marrow specimen from a patient with a

history of plasma cell myeloma who presents for a pre-transplant evaluation. The majority of plasma cells (6% of total white cell count) are abnormal plasma cells *shown in red* that express kappa cytoplasmic light chain with variable CD45, with CD56 and CD138, and without CD19 or CD38. This patient has received prior therapy, including the anti-CD38 monoclonal antibody daratumumab. Note, the dot plot illustrated in panel **H** shows all viable cells. (Abnormal plasma cells are *highlighted in red*; all other cells are *gray*.) No cells in this marrow specimen express CD38. As CD38 has an expected pattern of expression on several normal marrow populations (including normal myeloid progenitors and normal hematogones (Figs. 56-7 and 56-10), knowledge of the prior therapy is critical when evaluating antigen expression in these populations. Moreover, in this setting, it is critical that plasma cell identification include evaluation for antigens beyond the targeted CD38.

Cytogenetics and Molecular Studies

Karyotype analysis of the bone marrow is useful when a clonal population similar to the patient's original neoplastic clone is identified, but the low mitotic rate of many low-grade lymphomas results in many false-negative results. The addition of interphase

FISH is one method of overcoming this problem and is useful in detecting lymphoma-associated translocations. Neither karyotype nor FISH analysis can detect T-cell or B-cell–associated gene rearrangements that are not associated with translocations or other clonal abnormalities.

A subset of lymphomas has recurring cytogenetic abnormalities that make them ideal for evaluating residual disease by PCR.[125] PCR tests directed against specific translocations offer a sensitivity similar to that of patient-specific gene rearrangement testing but do not require the development of primers specific to an individual patient. One of the most commonly studied translocations is the major breakpoint region of t(14;18)(q32.33;q21.3), involving the IGH gene of chromosome 14 and the *BCL2* gene of chromosome 18. This translocation occurs most commonly in follicular lymphomas and a subset of large cell lymphomas. Approximately half of the translocations may be detected by PCR for this breakpoint, and a subset of other cases can be detected with primers directed against the other cluster regions of this translocation.[263] However, t(14;18) has been reported to occur in some normal individuals when very sensitive methods are used.[264,265] Therefore, serial qPCR methods may be more useful in monitoring patients for residual disease to determine whether the load of t(14;18)-positive cells is increasing.[266] The major translocation cluster of t(11;14)(q13;q32.33) is detectable in approximately 40% of cases of mantle cell lymphoma, but many mantle cell lymphomas have variant translocations that are not easily detected by PCR.[267,268] However, in cases with known major translocation clusters, the PCR test is a reliable method of following patients for early relapse and is superior to four-color flow cytometry

in detecting MRD after immunochemotherapy.[268] The remaining patients can be followed using FISH studies. Although FISH analysis for t(11;14) does not detect the very low levels of disease detectable by PCR, it has a very low false-negative rate and is suitable for most patients with mantle cell lymphoma.[269] Similarly, the combined use of PCR and FISH analysis can be applied to the many other lymphoproliferative disorders with recurrent reciprocal translocations. The detection of residual molecular evidence of disease by FISH or qPCR in patients treated with autologous hematopoietic cell transplantation for follicular lymphoma is predictive of relapse.[270-272] However, some PCR-positive patients remain in remission, and quantitative assays are useful in better predicting disease behavior in these cases. In PCM, many patients have numerical chromosomal abnormalities or recurrent IGH-associated chromosomal abnormalities like t(11;14)(q13;q32), which can be monitored by FISH analysis[273,274]; however, this cannot detect very low levels of residual disease.

Molecular platforms that are more agnostic to the presence of specific translocations and therefore more universally applicable are being used more often to evaluate for residual disease in lymphoid and plasma cell disorders. Among the mature lymphoid neoplasms, molecular determination of MRD using these platforms has been most often used in CLL. Similar to B-ALL, the two most widely used molecular methodologies are allele-specific oligonucleotide (ASO), real-time qPCR, and high-throughput sequencing of the IGH gene. The former method is more labor-intensive and costly and has higher tendency to yield false-positive or false-negative results because of low-level amplification and potential emergence of a new clone or

subclone.[275] The latter NGS MRD platform uses multiplex PCR followed by sequencing to identify and quantify the patient-specific leukemia signature immunoglobulin heavy and light chain rearrangement of CLL cells in the diagnostic and post-treatment samples.[276] Compared with ASO real-time qPCR, the NGS-based assay uses consensus primers without the need of customized patient-specific primers, resulting in even higher sensitivity (1×10^{-6}) and broader applicability. However, NGS-based assays may have a disadvantage in MRD determination in germinal or post–germinal center B-cell derived lymphoid neoplasms because, in a significant percentage of these patients, clonal rearrangements might not be detected with the consensus IGH gene primers that are commonly used because of the abundant somatic hypermutations.[277]

CLL MRD quantification has been shown to be an independent prognostic marker of PFS and OS after chemoimmunotherapy and after allogeneic transplantation.[276,278] Several clinical trials demonstrated that patients achieving U-MRD had a longer PFS compared with that of patients with detectable MRD, suggesting MRD may be a prognostic factor with some therapies.[279-281] MRD of $\geq 10^{-6}$ measured by high-throughput NGS IGH sequencing at multiple time points, including 9, 12, 18, and 24 months posttransplant, predicts relapse and inferior disease-free survival after reduced-intensity allogenic bone marrow transplantation.[282] However, the beneficial utility of MRD determination does not seem to apply to patients receiving Bruton tyrosine kinase (BTK)-inhibitors.[283] Less than 10% of these patients achieve MRD-negativity, but they demonstrate good PFS compared with that of patients receiving other therapies with higher rates of complete

response and MRD-negativity. This suggests using only MRD test data for drug approvals may have limitations. Nevertheless, MRD is a useful prognostic tool to predict the outcome of patients with CLL in some settings and is now an accepted surrogate marker to assess treatment efficacy in randomized trials before clinical endpoints can be evaluated.[278] Despite this evidence, the role of MRD assessment in CLL is complex and multifactorial, and it has yet to be used to influence treatment decisions in routine CLL clinical practice. There are, however, emerging studies that suggest MRD and its kinetics can be used to guide the decision of when to stop treatment, determine those who may safely stop therapy, and identify newly diagnosed patients with CLL who might require a longer duration of therapy or additional agents to achieve more durable U-MRD remissions.[283,284] Its potential as an important biomarker in CLL necessitates continuous evaluation and further standardization of methodology, nomenclature, and reporting.[255]

MRD determination can also be applied to other lymphomas and PCM using similar methodologies. There is accumulating evidence that MRD status is a strong prognostic factor for PFS and OS in mantle cell lymphoma.[255,285-287] In PCM, assessment of MRD status, either by NGS or MRD flow cytometry, can further stratify patients achieving a complete remission and is predictive of PFS and OS in all phases of the disease.[288] MRD negativity, defined as ≤1 tumor cell in 100,000 cells (10^{-5}), is associated with superior PFS and OS in newly diagnosed and relapsed/refractory PCM and appears to be independent of cytogenetics risk and depth of clinical response at the time of MRD measurement.[289-294] Numerous clinical trials are ongoing to address the question of how to use MRD

as a surrogate endpoint to direct treatment.[295] Indeed, a new MRD status-based criteria to select patients with myeloma as transplant candidates has been proposed according to emerging clinical trial data.[296]

Increased understanding of the genomic landscape of chronic leukemias and lymphomas has prompted considerable interest in developing MRD tests based on detection and quantification of somatic mutations. Circulating tumor DNA (ctDNA) in plasma can serve as an important source of genetic materials for disease monitoring after therapy through this type of analysis. The sensitivity is limited by the error rates intrinsic to most conventional NGS techniques but can be enhanced through error correction using unique molecular identifiers (UMIs). ctDNA analysis allows a comprehensive genotyping of the disease from all the involved compartments, for a noninvasive serial analysis of clonal evolution, and possibly MRD investigation.[296] Its clinical utility has been demonstrated in several lymphoid malignancies, including CLL, diffuse large B-cell lymphoma, multiple myeloma, and other lymphomas.[297-301]

Other Bone Marrow Changes after Therapy

Necrosis

Bone marrow necrosis is a relatively uncommon finding, although the exact incidence is variable in the literature.[302,303] When present, however, it is most commonly associated with marrow involvement by malignancy and, less frequently, with infections, drugs, sickle cell disease, or other rare systemic abnormalities. The malignancies most

often associated with marrow necrosis are acute leukemias, especially ALL, high-grade non-Hodgkin and Hodgkin lymphomas, and metastatic tumors. Bone marrow necrosis is more common after chemotherapy, especially in lymphoid lesions, but it should not be attributed to the chemotherapy alone, because cytotoxic agents induce apoptosis and not necrosis. The presence of necrosis was correlated to worse response rates in both AML and ALL and worse survival rates in AML in one study.[304] Post-therapy necrosis usually involves complete marrow replacement by nonviable "ghost cells" with pyknotic nuclei and degenerative cytoplasm (**Fig. 56-18**). A careful examination should be performed to exclude the possibility of foci of viable, residual tumor in these patients. Areas of necrosis may be replaced by normal regenerating elements on follow-up specimens or by fibrosis in subsequent biopsies.

Patients who have undergone prior therapy are also at high risk for infections, and infectious causes of bone marrow necrosis must be considered. Special stains for organisms should be performed, especially when focal areas of necrosis are present in the marrow, even in the absence of granulomatous inflammation. If special stains are negative for organisms, repeat bone marrow aspiration for bacterial, fungal, and viral cultures should be considered if unsuspected necrotic foci are found that are not associated with a necrotic tumor. Post-therapy bone marrow necrosis caused by specific drugs is even less common but has been reported with interferon-α, ATRA, fludarabine, and G-CSF.[34,302,304]

Fibrosis

Bone marrow fibrosis accompanies marrow involvement by a wide variety of malignant neoplasms, including chronic MPNs, Hodgkin lymphoma, mast cell disorders, metastatic carcinoma, hairy cell leukemia, and acute leukemias.[305] A mild reticulin fibrosis is often present in the markedly hypocellular post-therapy marrow, but this fibrosis quickly resolves as the marrow cellularity returns. Reticulin fibrosis is often slightly increased in association with acute leukemia.[306,307] Except for the development of fibrosis as part of the resolution of marrow necrosis, marrow fibrosis usually decreases or disappears after treatment of the primary disease by either chemotherapy or hematopoietic cell transplantation.[306] Bone marrow fibrosis secondary to CML is also significantly decreased by treatment with imatinib,[151] although increased marrow fibrosis after treatment can also be seen in some patients, particularly those in the accelerated or blast phase.[150]

Development of marrow fibrosis after therapy may represent recurrence of disease or metastasis, or it may be secondary to non-neoplastic sequelae of the therapy. These secondary causes are similar to the causes of marrow fibrosis in any marrow,[305] such as fibrosis related to renal osteodystrophy, hypoparathyroidism or hyperparathyroidism, or vitamin D deficiency. Fibrosis may occur at the site of a prior biopsy or healing trauma. Patchy areas of fibrosis are also seen with bone marrow involvement by mast cell disease,[308,309] which may accompany other hematologic malignancies at diagnosis or relapse.

Serous Atrophy/Gelatinous Transformation

The predominance of gelatinous extracellular material with fat atrophy and associated marrow hypoplasia is termed serous atrophy or gelatinous transformation of the bone marrow. The material is light blue to pink with a mucoid or myxoid appearance, and residual hematopoietic elements may be present in chords. The gelatinous material is positive for Alcian blue, with staining eliminated after hyaluronidase treatment (**Fig. 56-19**).[310] This change is associated with starvation, wasting diseases, which include weight loss secondary to malignancies, and starch-free diets. The edema and deposition of fibrin and pink proteinaceous material in an aplastic marrow after myeloablative chemotherapy may mimic fat serous atrophy, but the presence of eosinophilic gelatinous material of serous atrophy has only rarely been reported after chemotherapy. When it does occur, it differs from the cachexia-associated form of serous atrophy in the lack of bone marrow fat atrophy. The gelatinous material differs from fibrin by its reactivity for Alcian blue, and it is a transient phenomenon in postchemotherapy marrow.[311]

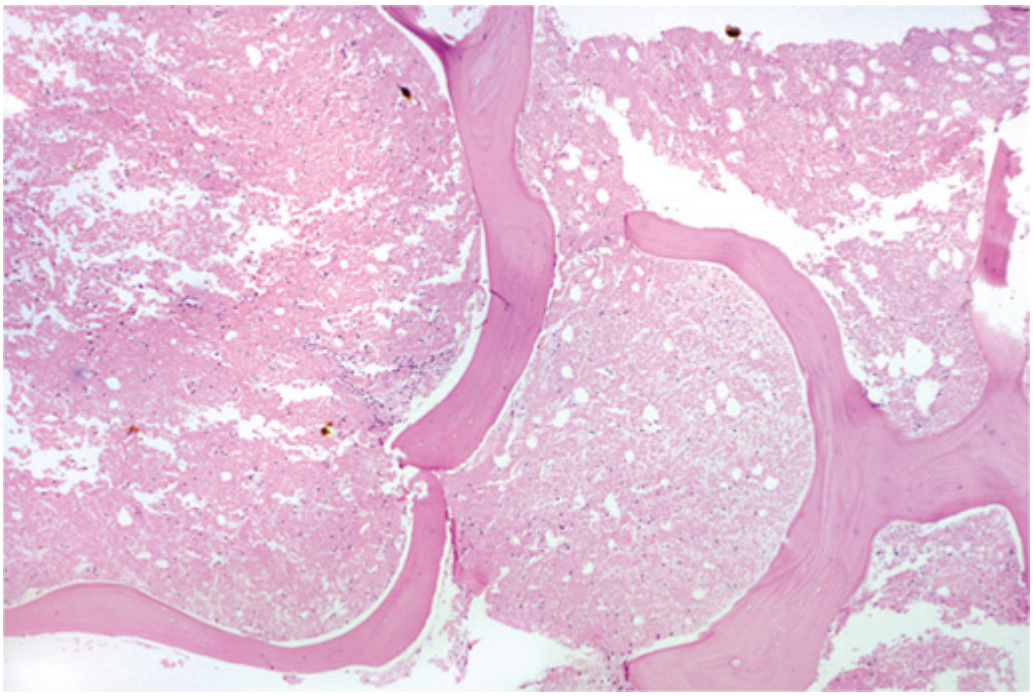

FIGURE 56-18 Extensive bone marrow necrosis after therapy for acute lymphoblastic leukemia.

Solid Tumors

Patients treated for solid tumors with or without prior bone marrow involvement may show transient aplasia and regeneration, similar to postchemotherapy changes in other diseases. If there was prior bone marrow involvement, foci of fibrosis or tumor necrosis may be present. Metastatic disease after therapy is usually detected by morphologic evaluation of bone marrow biopsy material (**Fig. 56-20**), which may be supplemented by immunohistochemistry.[312] Most metastatic tumors are associated with bone marrow fibrosis, and the detection of keratin-positive cells within these areas of fibrosis is useful to confirm the presence of metastatic carcinoma. Unusual patterns of recurrent disease include maturation of

neuroblastoma with focal ganglion-like cells (differentiation) embedded in fibrosis and metastatic tumors that are not associated with marrow fibrosis. Identification of residual tumor cells may be difficult in the latter case. The most common metastatic tumors that involve the bone marrow without fibrosis are lobular breast carcinoma and neuroblastoma.[313] Recommendations for reporting bone marrow samples in patients being treated for neuroblastoma are that immunohistochemistry with at least two antibodies (e.g., synaptophysin and chromogranin A) be performed on at least three levels of bilateral core biopsies, which can help identify small areas of persistent disease (**Fig. 56-20**). Persistent tumor should be quantitated in intervals of 5% (0%, ≤5%, >5%–<10%, etc.).[314] The individual tumor cells of lobular carcinoma may have more abundant cytoplasm than normal bone marrow elements, and the presence of individual signet ring cells should raise suspicion for involvement by lobular carcinoma. Keratin immunohistochemistry is advised for all bone marrow biopsy specimens from patients with a history of lobular breast carcinoma to allow the detection of individual metastatic cells (**Fig. 56-21**).[315]

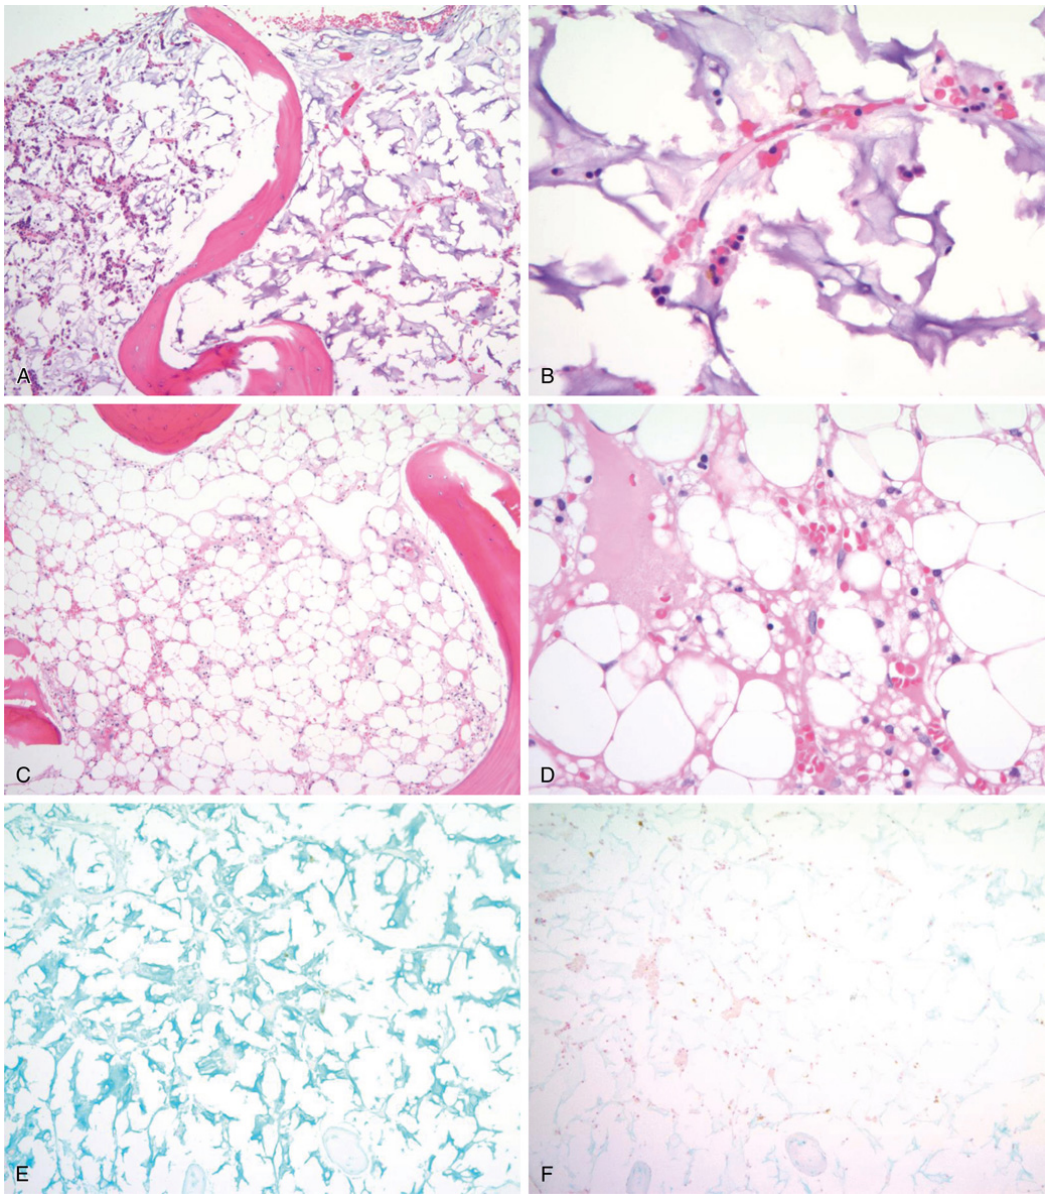

FIGURE 56-19 Serous atrophy/gelatinous transformation of bone marrow from an elderly patient with dementia (**A** and **B**) shows marrow hypocellularity and replacement by bluish acellular material when compared with the hypocellularity, edema, and fibrillary eosinophilic material (**C** and **D**) present in a patient post-induction chemotherapy for acute myeloid

leukemia. Gelatinous transformation will stain positive for Alician blue **(E)**, but stromal damage will not. Staining is decreased after hyaluronidase treatment **(F)**.

Several studies have evaluated the detection of occult metastatic disease in the bone marrow in tumors other than lobular breast carcinoma.[316-318] The detection of these occult tumor cells by immunohistochemistry has been associated with early relapse in several tumor types, including breast and ovarian carcinoma, and the detection of bone marrow disease in breast carcinoma may be of even more prognostic significance than the detection of lymph node metastasis.

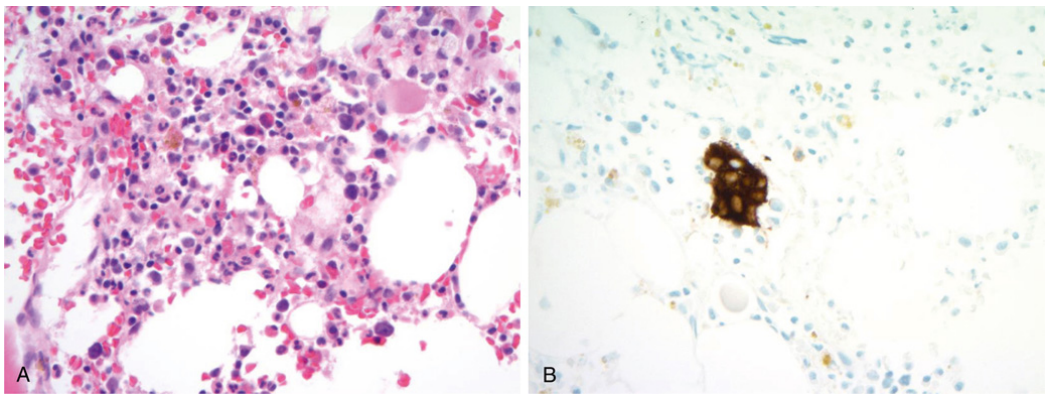

FIGURE 56-20 Small focus of recurrent neuroblastoma in the bone marrow **(A)**, highlighted by staining for synaptophysin **(B)**.

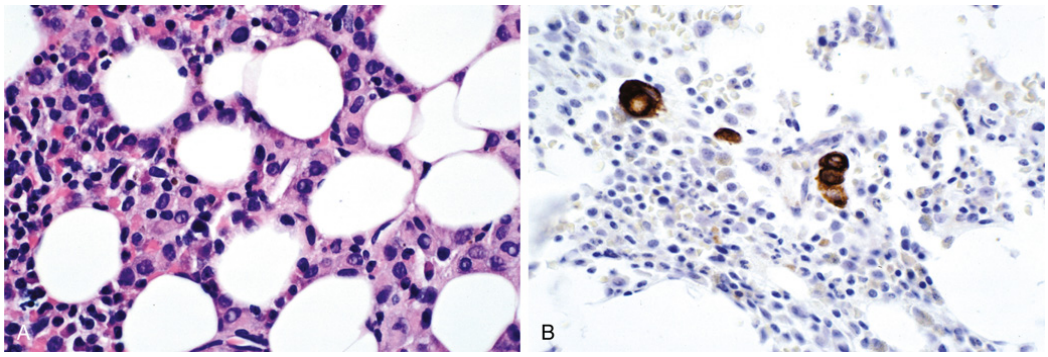

FIGURE 56-21 Metastatic lobular breast carcinoma forms less-obvious tumor aggregates in the bone marrow.A, Interstitial tumor infiltration is present in the upper portion of the specimen. **B,** Keratin immunohistochemistry of another case shows individual tumor cells in the marrow.

Late Effects of Therapy, Including Secondary Malignancies

In addition to disease recurrence, patients receiving high-dose chemotherapy and hematopoietic cell transplantation have other therapy-related complications. After allogeneic transplantation for leukemia or aplastic anemia, most patients are considered cured of the primary disease if they have not relapsed within 2 years.[319] However, they often experience other complications, such as graft-versus-host disease, veno-occlusive disease, sexual dysfunction, and impaired glucose tolerance and dyslipidemia.[319-324] Other than possible graft failure, however, these syndromes do not significantly affect the bone marrow.

A reactive peripheral blood lymphocytosis is common after transplantation. This lymphocytosis typically corresponds to large

granular lymphocytes and can mimic T-cell large granular lymphocytic leukemia (T-LGL).[325,326] In the bone marrow, these reactive cells may be seen in an interstitial pattern. Unlike cases of T-LGL leukemia, this reactive proliferation of LGLs typically is not accompanied by cytopenias, and though these LGLs correspond to CD8-positive/CD57-positive T cells, flow cytometry will not detect abnormalities in antigen expression. In many patients, these reactive LGLs can persist for years without significant consequence.

Patients who are treated with ibrutinib, a Bruton TKI, for CLL/SLL can have a transient large cell transformation if therapy is interrupted. This has been reported in the bone marrow and lymph nodes, and caution should be used in interpreting any new large cell proliferations in this setting.[327]

Secondary malignancies after solid organ transplantation, radiation therapy, or high-dose chemotherapy with hematopoietic cell transplantation are becoming increasingly common.[319,328-334] Although radiation-induced sarcomas may secondarily involve the bone marrow, such involvement is uncommon. However, therapy-related MDS, acute leukemia, and lymphoproliferative disorders may first be diagnosed on bone marrow examination.

Therapy-related myeloid neoplasms are fairly common in patients who have survived high-dose chemotherapy with hematopoietic cell transplantation (**Fig. 56-22**). Approximately 10% to 20% of cases with AML, MDS, and myelodysplastic neoplasm/MPN are therapy-related.[335] The mechanisms of these neoplasms are thought to associate with a direct consequence of mutational events by cytotoxic therapy or via the selection of a myeloid clone with a mutator phenotype that has a markedly elevated risk for mutational events.

These neoplasms are aggressive diseases with poor clinical outcomes, even in the case of therapy-related MDS without an increase in blast cells, and are frequently associated with an abnormal karyotype and a complex karyotype.

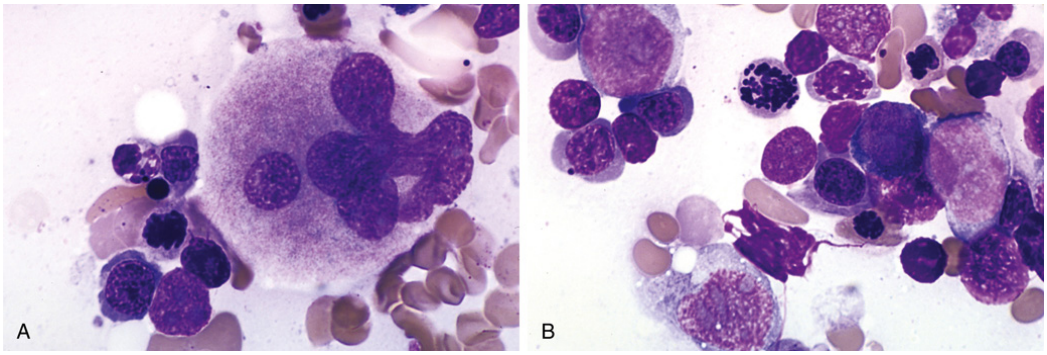

FIGURE 56-22 Therapy-related myelodysplastic syndrome.(A) and **(B)** are examples of cases that often show pronounced dyspoietic changes, including abnormal nuclear lobation of megakaryocytes and bizarre nuclear changes of erythroid precursors.

Two main causative cytotoxic agents associated with therapy-related AML and MDS are alkylating agents and topoisomerase II inhibitors.[330,335-339] Disease associated with alkylating agents usually has a long latency period of 5 to 10 years and may be associated with the development of cytopenias and MDS or AML with multilineage dysplasia. These cases are usually associated with deletion of a portion of chromosome 5 and/or 7, monosomy 5 and/or 7, or other unbalanced translocations. These chromosomal abnormalities may be detectable before the development of morphologic features of dysplasia, and cytogenetic studies should be

performed on all cases of suspected therapy-related disease to detect this morphologically subtle presentation. Disease after topoisomerase II inhibitor therapy usually does not show changes of multilineage dysplasia and presents as an overt AML. Morphologically, most of these patients have monocytic or myelomonocytic features. These leukemias usually have a shorter latency period of 1 to 5 years and are associated with balanced cytogenetic translocations involving 11q23.3 (*KMT2A* gene) or 21q22.3 (*RUNX1* gene). A variety of other cytogenetic abnormalities may occur in therapy-related leukemia and MDS, including many different balanced translocations.[335,339] Patients with de novo AML with t(8;21), t(15;17) and inv(16) are known to have favorable prognosis. Although less frequent, these cytogenetic abnormalities account for approximately 10% of therapy-related myeloid neoplasms. Patients with t(8;21), t(15;17), and inv(16) in therapy-related myeloid neoplasms have poorer clinical outcomes than those of patients with the same abnormality in de novo disease.[338,340]

Mutational analysis using NGS has shown *TP53* mutations are more frequent in therapy-related myeloid neoplasms (20%–40%) than in de novo AML or MDS (5%–10%). Studies have reported this selective enrichment is a result of the preferential expansion of preleukemic clones harboring a somatic *TP53* mutation after cytotoxic therapy. *TP53* mutations are associated with complex karyotype and poor prognosis. Less frequent mutations observed included *TET2* (10%–37%) and *IDH1/IDH2* (around 7% and 12% in therapy-related MDS and AML, respectively). Other recurrent mutations found in a study of therapy-related myeloid neoplasms

included mutations in *DNMT3A* (~20%), *FLT3* (8%–16%), and *NPM1* (18%).[335,341-344]

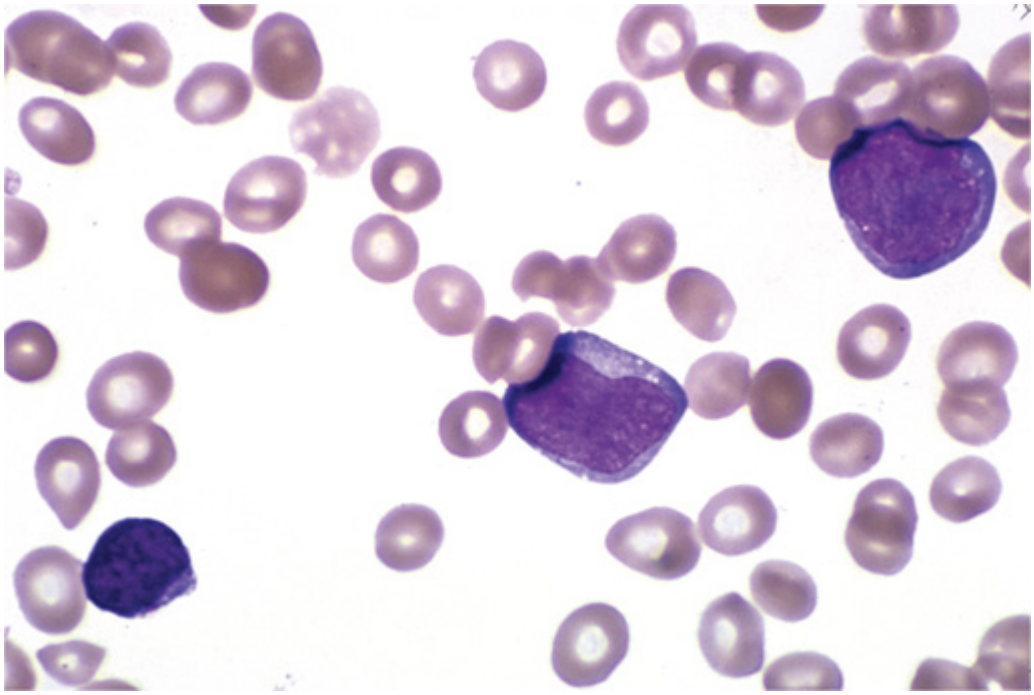

FIGURE 56-23 Therapy-related acute lymphoblastic leukemia. Blasts often show aberrant expression of the myeloid-associated antigens CD15 and CD65 and rearrangements of the *KMT2A* gene.

Other therapy-related leukemias are less common but include MDS or AML associated with 17p deletions and *TP53* mutations, which most often occur after hydroxyurea therapy for essential thrombocythemia.[342-344] There are prominent dysplastic changes of the neutrophil series, with pseudo–Pelger-Hüet cells, monolobated neutrophils, and prominent vacuolated cytoplasm. Similar morphologic and cytogenetic changes have been described in a

subgroup of lymphoma patients with alkylating agent–related MDS and AML. Therapy-related ALL is also rare (**Fig. 56-23**),[345,346] but it occurs most often in patients treated with topoisomerase II inhibitors.[347] These leukemias are frequently of a pro–B-cell (CD10-negative) immunophenotype, with aberrant expression of the myeloid-associated antigens CD15 and CD65. They are usually associated with balanced translocations of the *KMT2A* gene, particularly t(4;11)(q21;q23); however, patients with amplification of *MLL* genes in addition to presence of complex karyotype have been reported.[348,349]

Donor-derived second malignancy after allogeneic hematopoietic stem cell transplantation is an extremely rare complication of transplantation.[275,276] Oncogenic transformation or premature senescence of transplanted donor cells in an immunosuppressed host and disruption of normal homeostasis after transplantation may be associated with donor-cell–derived malignancies. The incidence of donor-derived leukemia comprises less than 1% of cases. Reported cases have included acute myeloid or lymphoblastic leukemia, MDS, CML, and T-cell lymphoma.[241,350-353]

Posttransplant lymphoproliferative disorders (PTLDs), which are covered in detail in **Chapter 54**, may involve the bone marrow. Over half of patients who develop PTLDs after solid organ transplantation have bone marrow involvement, and bone marrow changes are more common in children than in adults with PTLDs.[354] Bone marrow involvement is associated with a poorer outcome. Aspirate smears tend to show an increased number of plasma cells. On the biopsy, the changes may range from aggregates of small lymphocytes or plasma cells without obvious atypia to aggregates of

large, atypical cells, usually with plasmacytoid features. Atypical cell infiltrates may be associated with fibrosis. The cellular infiltrate is usually of B-cell lineage, but plasmacytoid cells may be underrecognized owing to their lack of immunoreactivity with antibodies directed against CD20. In situ hybridization studies for Epstein-Barr virus–encoded RNA (EBER) are positive in most cases. Although less common, PTLDs that occur after bone marrow transplantation are highly aggressive B-cell proliferations associated with Epstein-Barr virus and usually have a large-cell or immunoblastic morphology.[355] These proliferations are associated with T-cell–depleted transplantation, unrelated donor transplantation, or HLA-mismatched–related donor transplantation, and they usually occur within the 1st year after transplantation.[329]

Pearls and Pitfalls

- Bone marrow specimens must always be interpreted in the context of the clinical setting.
- Slight increases in blast cells (>5%) do not always mean residual disease.
- Residual disease can be present in patients with less than 5% blast cells.
- Flow cytometry is useful in separating regenerating progenitors (blasts) from leukemic cells.
- Residual or recurrent leukemia is favored over regeneration when sheets of blasts are present on smears or when blasts outnumber promyelocytes.

- Growth factor therapy may be a factor in patients with numerous promyelocytes with distinct perinuclear hofs.
- Aggregates of CD34-positive or TdT-positive cells on bone marrow biopsy material favor leukemia over regeneration or hematogones.
- Dyserythropoietic changes, including ring sideroblasts, during or shortly after chemotherapy are not sufficient for an interpretation of MDS.
- Hematogones should be considered when a small lymphoid cell proliferation is present in children.
- A spectrum of lymphoid cells that, by morphology or antigen expression, resemble precursor B-cell development is more characteristic of hematogones than leukemic cells.
- Hematogones do not show cytogenetic abnormalities or aberrant immunophenotypes.
- Never rely on a single feature to exclude the presence of disease.
- Consider the sensitivity and pitfalls of any test used, especially ancillary studies.
- Morphologically normal bone marrow may continue to show the Ph chromosome in patients treated for CML.
- MRD detection as measured by flow cytometry or molecular methods is emerging as an important modality in monitoring treatment response, prognostication of patients, and precise tailoring of therapy in acute leukemias, mature lymphoid neoplasms, and chronic myeloid neoplasms.

- By flow cytometry, separation of leukemic blasts from normal progenitors relies on recognizing differences in immunophenotype exhibited by leukemic cells compared with normal antigenic changes that characterize hematopoiesis.
- The best molecular markers for evaluating MRD in AML are *RUNX1*::*RUNXT1, CBF*::*MYH11, PML*::*RARA,* and mutated *NPM1*. Highly sensitive MRD detection using these markers can be achieved through real-time qPCR.
- Mutations in genes most frequently associated with clonal hematopoiesis (*DNMTA, TET2,* and *ASXL1*) are not suitable for MRD assessment in AML.
- NGS of immunoglobulin genes provides a highly sensitive platform to identify MRD in lymphoid neoplasms.
- Mutation profiling of cfDNA allows evaluation of residual disease, helps predict relapse, and offers a better evaluation of clonal heterogeneity and evolution. The molecular detection of very low levels of t(15;17), inv(16), and t(8;21) fusion transcripts at a single time point after therapy does not necessarily predict relapse, though sequential reading showing increasing levels of a fusion transcript do suggest relapse.
- Patients treated for multiple myeloma or CML may have small, decreasing but detectable populations of residual clonal disease for several months after transplantation, which may convert to molecular remission without additional therapy.

Chapter 57: Non-hematopoietic Neoplasms and Other Lesions of the Bone Marrow and Lymph Nodes

Lawrence R. Zukerberg†, and Aliyah R. Sohani

OUTLINE

Introduction

Metastatic Tumors of the Bone Marrow

- **Invasive Breast Carcinoma**
- **Carcinoma of the Lung**
- **Metastatic Prostate Cancer**
- **Carcinomas of the Stomach and Colon**
- **Renal Cell Carcinoma**
- **Melanoma**
- **Pediatric Small Round Blue Cell Tumors**

Primary Tumors of Bone

Ewing's Sarcoma

Bone and Cartilage–Forming Tumors

Vascular Tumors Involving Bone

Hemangiomas

Epithelioid Hemangioendotheliomas

Other Soft-Tissue Tumors Involving Bone

Malignant Lymphomas Involving Bone and Bone Marrow

Benign Lesions of Bone

Benign Tumor-like Lesions

Metaphyseal Fibrous Defect (Nonossifying Fibroma) and Fibrous Dysplasia

Paget's Disease

Chronic Osteomyelitis

Metabolic Bone Diseases

Metastatic Tumors to Lymph Nodes

Histologic Features of Metastatic Tumors

Characteristic Biological Patterns of Metastasis

- Role of Immunohistochemistry in the Diagnosis of Metastatic Tumors
- Nonlymphoid Tumors With Prominent Reactive Lymphoid Components

Benign Lymph Node Inclusions

- Epithelial and Mesothelial Inclusions in Lymph Nodes
- Keratin-Positive Fibroblastic Reticular Cells
- Nevus Cell Aggregates

Mesenchymal Proliferations in Lymph Nodes

- Vascular Transformation of Lymph Node Sinuses and Lymphatic Proliferations
- Mixed Smooth Muscle–Vascular Proliferations
- Inflammatory Pseudotumor of Lymph Nodes
- Kaposi Sarcoma
- Vascular Tumors
- Metastatic Sarcomas of Other Types
- Bone Marrow Hematopoietic Elements and Tumors Involving Lymph Nodes

Conclusion

Introduction

The bone marrow, the primary site of hematopoiesis, may contain hematopoietic or non-hematopoietic tumors and also frequently reflects metabolic disturbances. The occurrence of bone marrow metastases is strongly influenced by microenvironmental factors that favor the engraftment of certain malignancies.[1] Bone marrow involvement by metastatic tumor is often referred to as myelophthisis and presents in the blood, usually subtly, as leukoerythroblastic anemia with left-shifted granulocytic precursors, nucleated red cells, teardrop red cells, and large platelets. Symptoms related to cytopenias, metabolic disturbances, and occupation of space (such as bone pain) may mimic leukemias and lymphomas. Imaging studies are often helpful, but a bone marrow examination is usually required to directly visualize the process. Bone marrow examination should include both aspiration and biopsy, and multiple sites (usually the bilateral iliac crests) may need sampling.

Similarly, nonlymphoid elements are frequently present in biopsied or excised lymph node specimens. This chapter reviews the most commonly encountered tumors and non-neoplastic lesions of bone marrow and lymph nodes and provides an update on studies useful in distinguishing them. Each section focuses on metastases because they present the most diagnostic difficulty and benign tumor-like lesions that may be in the differential diagnosis of metastatic tumors. Mesenchymal and vascular proliferations are also discussed, including those intrinsic to each organ.

Table 57-1

AFB, Acid-fast bacillus; *ALK,* anaplastic lymphoma kinase; *EM,* electron microscopy; *EMA,* epithelial membrane antigen; *FDC,* follicular dendritic cell; *HHV-8 LANA-1,* human herpesvirus 8 latency-associated nuclear antigen-1; *IDC,* interdigitating dendritic cell; *LCA,* leukocyte common antigen; *NSE,* neuron-specific enolase; *PAS,* periodic acid–Schiff; *PLAP,* placental alkaline phosphatase; *TdT,* terminal deoxynucleotidyl transferase.

Metastatic Tumors of the Bone Marrow

The most common metastatic tumors of the bone and bone marrow are carcinoma of the breast, lung, and prostate, together constituting two-thirds of cases.[2] Each of these is present in up to 20% of patients with the primary tumor. Other metastases seen at lower frequencies include adenocarcinoma of the stomach and colon, melanoma, renal cell carcinoma, ovarian and testicular carcinoma, transitional cell carcinoma, rhabdomyosarcoma, Ewing's sarcoma, and vascular tumors. Childhood tumors, including rhabdomyosarcoma, neuroblastoma, retinoblastoma, medulloblastoma, and Ewing's sarcoma, frequently involve the bone marrow.[3,4] Metastatic tumors are best diagnosed and classified at their primary site; however, immunohistochemistry (IHC) provides an adjunct to morphology when the primary site is not known (**Table 57-1**). However, technical issues related to decalcification of bone marrow core biopsy specimens may lead to suboptimal staining.

Invasive Breast Carcinoma

In the 5th edition of the *World Health Organization (WHO) Classification of Tumours of the Breast,* invasive breast carcinoma is classified into a number of categories and subcategories.[5,6] By IHC, tumor cells stain for low–molecular-weight keratin, epithelial membrane antigen (EMA), and often for carcinoembryonic antigen (CEA), B72.3, and BCA-225.[7] Involved bone marrow may show abundant tumor nests, but areas of inconspicuous clusters and/or extensive fibrosis are also frequent (**Fig. 57-1A–D**). Microenvironmental factors strongly influence bone marrow involvement in this disease and may be altered by bisphosphonate drugs.[8] Detection of disseminated tumor cells in the bone marrow, most often by IHC, identifies high-risk patients and those who may benefit from bisphosphonate therapy.[9]

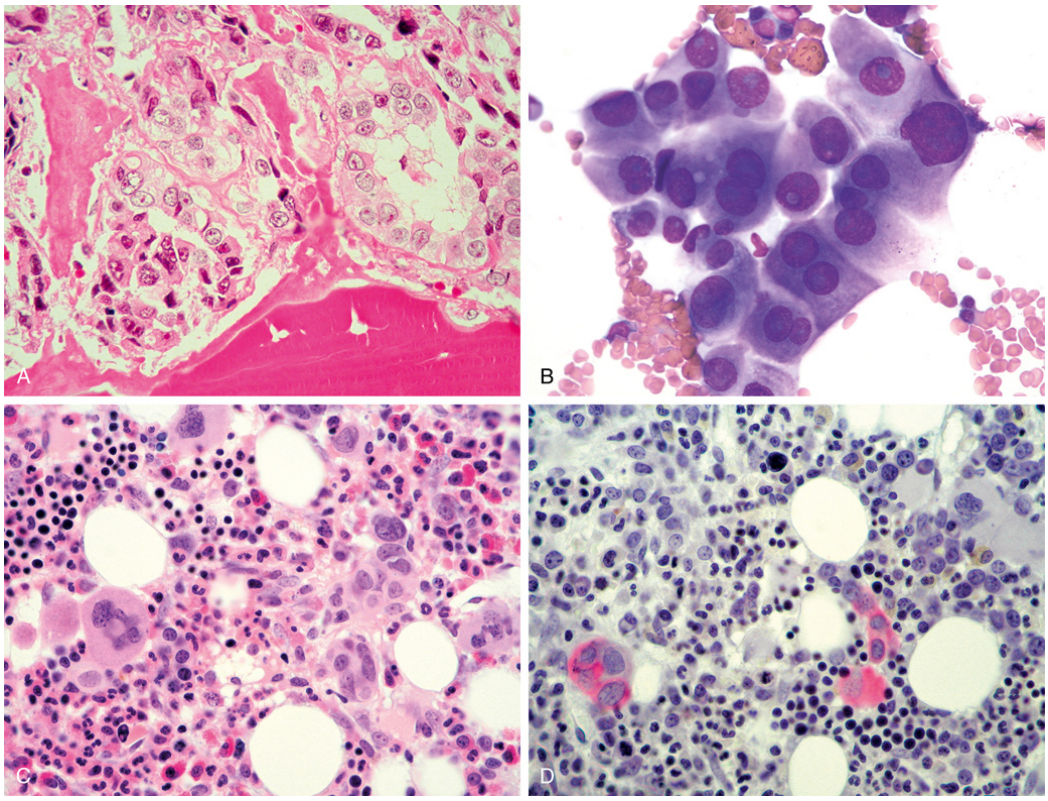

FIGURE 57-1 Metastatic adenocarcinoma of the breast in a bone marrow biopsy **(A)** and a bone marrow aspirate smear **(B)**. **C,** Another bone marrow biopsy shows inconspicuous involvement by metastatic breast carcinoma. **D,** The same biopsy shows the tumor cells highlighted by a pan-keratin stain.

Carcinoma of the Lung

Carcinoma of the lung involves the bone marrow, with frequency also varying by histologic type. Small-cell carcinoma most frequently metastasizes to the bone marrow (~20%), followed by squamous cell carcinoma (3%–15%) and adenocarcinoma (5%–10%).

Small-cell carcinoma cells resemble blasts but show frequent clustering and nuclear molding (**Fig. 57-2**). They label for pan-keratins, CK7, chromogranin, and synaptophysin. Patients frequently exhibit neuroendocrine syndromes.[7,10] Carcinoid tumors may also rarely metastasize to the bone marrow.

Squamous cell carcinoma is distinctive in the bone marrow biopsy but usually does not appear in aspirates, which may be acellular. Nests of cohesive tumor cells label for pan-keratins, CK7, CK5/6, and p63 and are often embedded in a fibrous background.

Adenocarcinomas (**Fig. 57-3**) are increasingly common in the lung and label for pan-keratins, CK7, napsin A, and TTF-1.[11,12] Morphologic classification; molecular and/or IHC determinations of *EGFR*, *KRAS*, and anaplastic lymphoma kinase *(ALK)* status; and assessment of PD-L1 expression by IHC are clinically indicated for assignment of targeted therapy, usually from a primary site.[13] Detection in metastatic sites may be performed by IHC or fluorescence in situ hybridization (FISH), but there is significant intratumor variability, with metastases often not reflecting the primary site.[2]

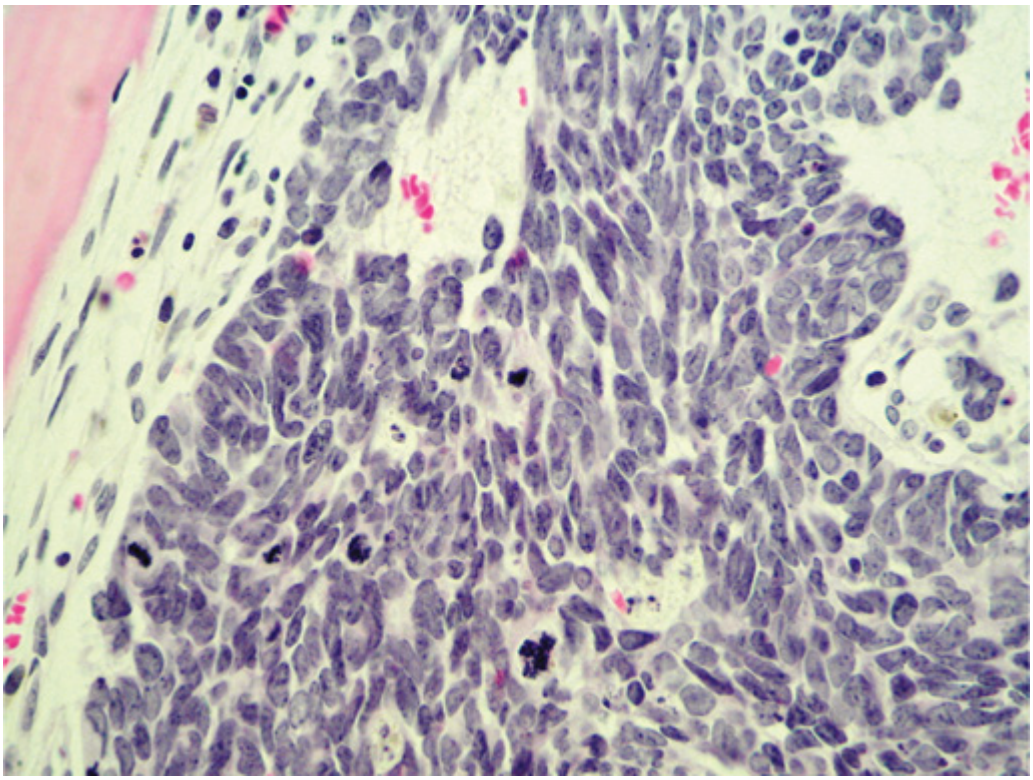

FIGURE 57-2 Small-cell carcinoma of the lung, metastatic to the bone marrow.

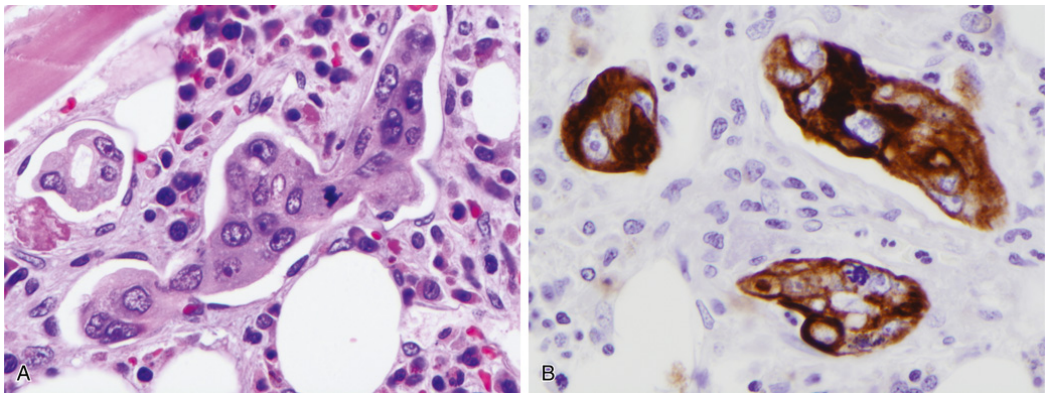

FIGURE 57-3 Metastatic adenocarcinoma of the lung in a bone marrow biopsy **(A)** expressing cytokeratin 7 **(B)**.

Metastatic Prostate Cancer

Metastatic prostate cancer most commonly involves bone marrow.[14] Although primary prostate tumors are frequently well-differentiated adenocarcinomas with small acinar formation, less well-differentiated forms tend to metastasize, particularly moderately differentiated forms with fused glands, cribriform or papillary formations, or loss of discernible gland formation (**Fig. 57-4**). Often, the diagnosis is suggested by serum screening for prostate-specific antigen (PSA) and confirmed by prostate biopsy, but it also appears as bone involvement by adenocarcinoma of unknown primary origin. IHC is usually positive for PSA, prostatic acid phosphatase, and pan-keratins. Poorly differentiated tumors negative for PSA and prostatic acid phosphatase may label for prostate-specific membrane antigen and prostein (P501S).[15]

Carcinomas of the Stomach and Colon

Most carcinomas of the stomach are adenocarcinomas of intestinal or diffuse types, though they may include other variants and a lymphoepithelioma-like pattern with abundant lymphocytes may be seen.[16] IHC shows expression of pan-keratins, EMA, CEA, CK20, CK7, and CA19-9.

Most colorectal carcinomas are moderately differentiated adenocarcinomas (**Fig. 57-5**).[17] These tumors label for cytokeratins (typically positive for CK20 but negative for CK7), CEA, villin, CDX2, and tumor-associated glycoprotein (TAG-72).[7] A small-cell variant labels with neuron-specific enolase (NSE) and synaptophysin.[17]

Renal Cell Carcinoma

Renal cell carcinoma often involves bone in advanced stage, occurring in one-third of patients with renal cell carcinoma who are enrolled in clinical trials. Bisphosphonates have been used for treatment but may be supplanted by new targeted agents.[18] Diagnostic IHC includes pan-keratins, CD10, RCC, PAX2, and PAX8.[19]

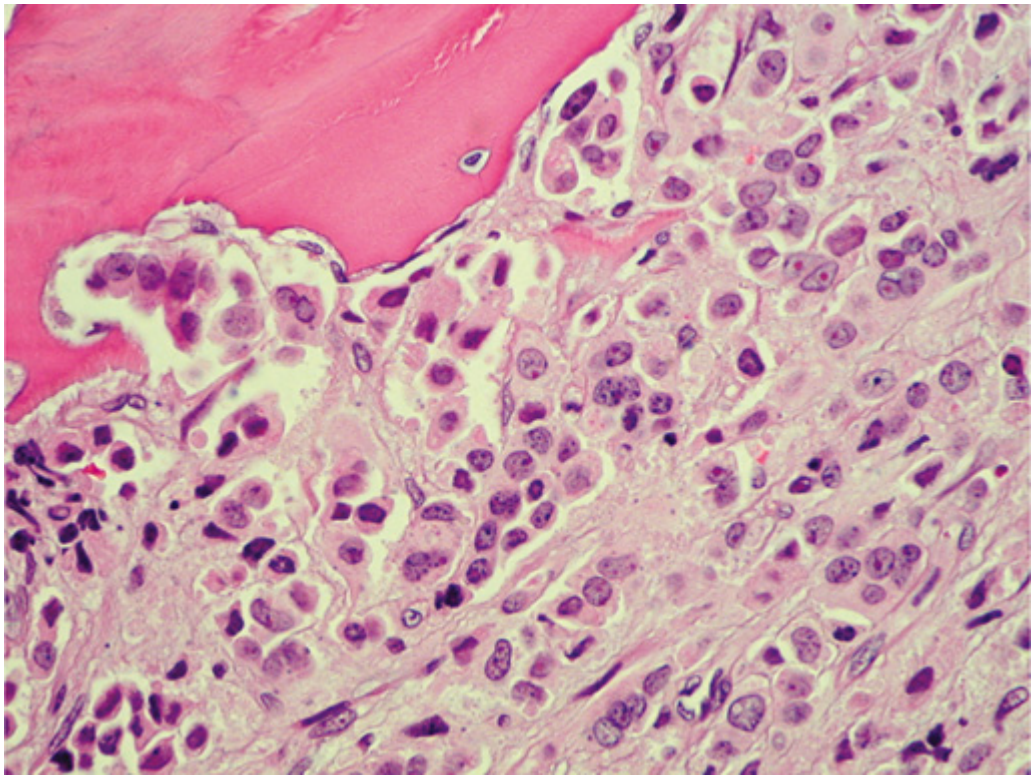

FIGURE 57-4 Metastatic prostate cancer in a bone marrow biopsy.

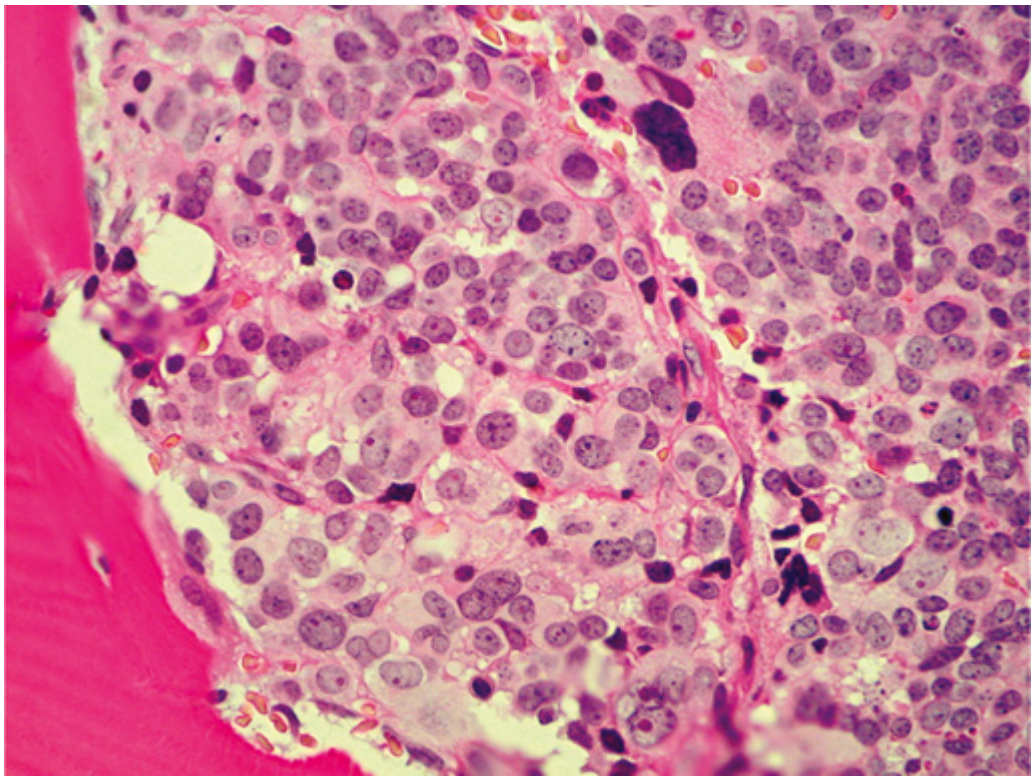

FIGURE 57-5 Bone marrow biopsy specimen extensively involved by metastatic colon carcinoma.

Melanoma

Melanoma frequently mimics other metastatic tumors, and although melanin production is helpful, it is uncommon in bone marrow metastases. Tumor cells may resemble large-cell lymphoma with immunoblastic, plasmablastic, or anaplastic morphology; may mimic plasma cell myeloma, including plasmablastic plasma cell myeloma; or may exhibit sarcomatoid features. Therefore, melanoma should be in the differential diagnosis of any anaplastic or poorly differentiated tumor. IHC staining for S-100 protein, HMB-45, and melan-A (MART-1) is usually diagnostic, although HMB-45 is negative in

desmoplastic melanoma.[20] *BRAF* V600 mutations in metastatic melanoma are targetable with anti-BRAF medications, and these may be detected in small biopsies by IHC.[21]

Pediatric Small Round Blue Cell Tumors

Pediatric small blue cell tumors generally require bone marrow examination for staging purposes, and results have significant effects on treatment and prognosis. Most of these tumors show highly variable patterns of involvement, sometimes with extensive disease at one site but undetectable involvement nearby.

Rhabdomyosarcoma, the most common soft-tissue sarcoma in children, is derived from skeletal muscle cells and bears myogenic proteins. Clinically relevant types include embryonal alveolar and rhabdomyosarcoma. Treatment and prognosis are based on age, stage, histology, and molecular or cytogenetic features, with a *FOXO1* translocation involving chromosome 13 accounting for poor prognosis in alveolar histology.[22] Bone marrow involvement is seen in 25% to 30% of patients, with an increased frequency of alveolar histology (50%).[23,24] Tumor cells in the bone marrow are often small to medium-sized blastoid cells, present singly or in small clusters, with an eosinophilic granular cytoplasm (**Fig. 57-6**). Hemophagocytosis and presentations resembling acute leukemia may occur.[25-31] Tumor cells label for desmin, muscle-specific actin, myo-D1, and myogenin.[32]

Neuroblastoma and related differentiated tumors, ganglioneuroblastoma and ganglioneuroma, occur primarily in young children. Neuroblastomas are most commonly primary to the adrenal cortex, abdominal or thoracic sympathetic ganglia, neck, and

pelvis, and they may be multifocal. Metastatic spread is both lymphatic and hematogenous, with bone marrow involvement common, seen in more than 50% of patients at diagnosis in some series.[33] Bilateral bone marrow biopsy and aspiration is recommended for staging. An adequate bone marrow specimen contains a biopsy of at least 1 cm in length and an aspirate containing spicules. Histology shows primitive neuroblasts, with varying Schwann and ganglion cells. Homer-Wright rosettes may be present and consist of neuroblasts surrounding a tangle of neuropil (**Fig. 57-7**). Fibrillary stroma is present in most cases, and Schwann cells with organized fascicles of neuritic processes and fibrosis are present in cases with ganglioneuromatous components. Aspirate smears should be carefully examined for small clusters of large blastoid cells.

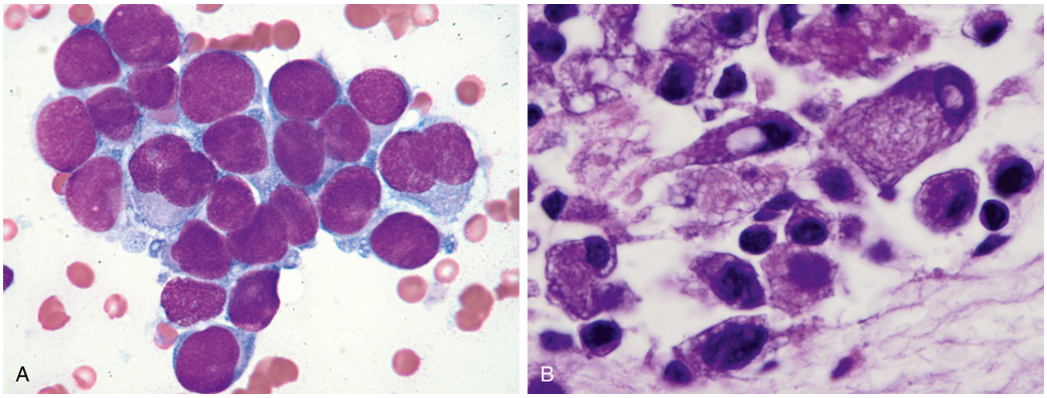

FIGURE 57-6 Metastatic rhabdomyosarcoma in bone marrow aspirate smears **(A)** and bone marrow biopsy **(B)**.

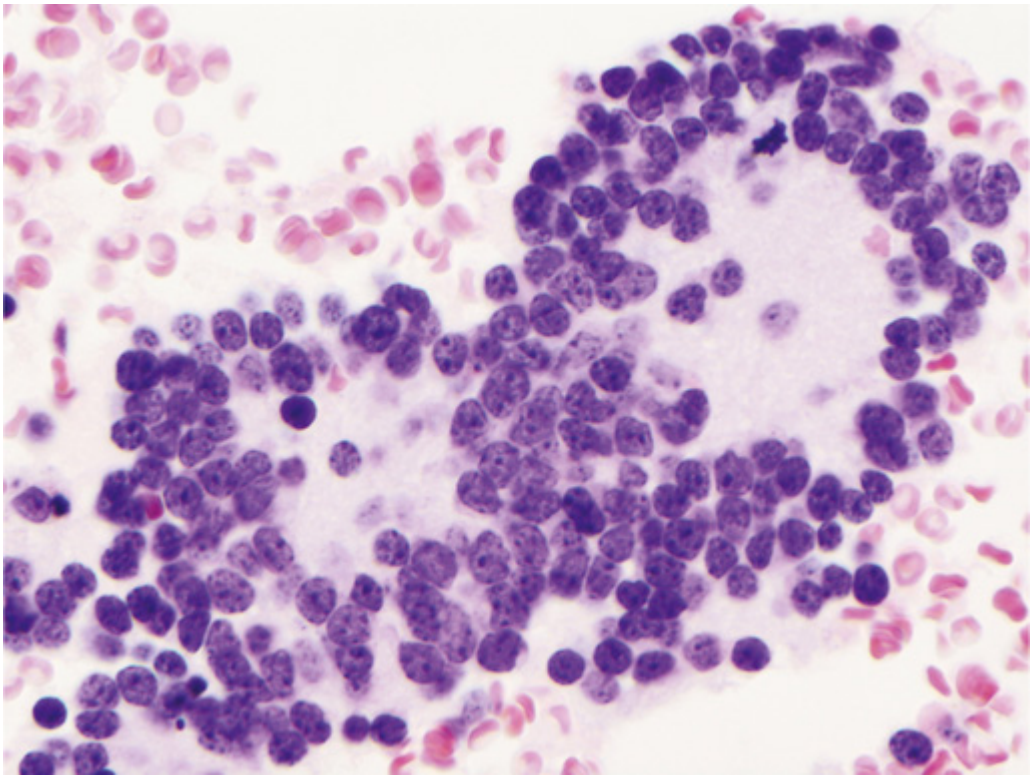

FIGURE 57-7 Rosettes of metastatic neuroblastoma in a clot section of bone marrow.

IHC may be helpful in identifying tumor cells, particularly in small biopsies or cases with focal involvement. NSE and CD56 are usually positive, S-100 labels Schwann cells, synaptophysin labels differentiated neuroblasts and ganglion cells, and chromogranin labels ganglion cells. Myelofibrosis may be present at diagnosis, and neuroblastoma may morphologically resemble acute leukemia (**Fig. 57-8**). Presence of differentiating ganglion cells in bone marrow metastases may be prognostically favorable.[34] After chemotherapy, a differentiated tumor with ganglion cells and stroma without neuroblasts has no negative prognostic influence.[35]

Retinoblastoma is an aggressive childhood tumor of the eye.[36] It is one of the most common eye tumors and the most common in

children. It is associated with mutations of the tumor suppressor retinoblastoma *(RB)* gene on chromosome 13q14 and usually presents before the age 5 years as a white light reflex. Disseminated disease usually presents in the bone marrow or central nervous system (CNS), but the actual incidence of marrow involvement is less than 10%, and the value of routine bone marrow examination is controversial. Histology varies from undifferentiated small blue cells to more differentiated forms with Homer-Wright and Flexner-Wintersteiner rosettes. By IHC, expression of rhodopsin, rhodopsin kinase, transducin, S antigen, GFAP, S-100, vimentin, and CD56 is seen.[37]

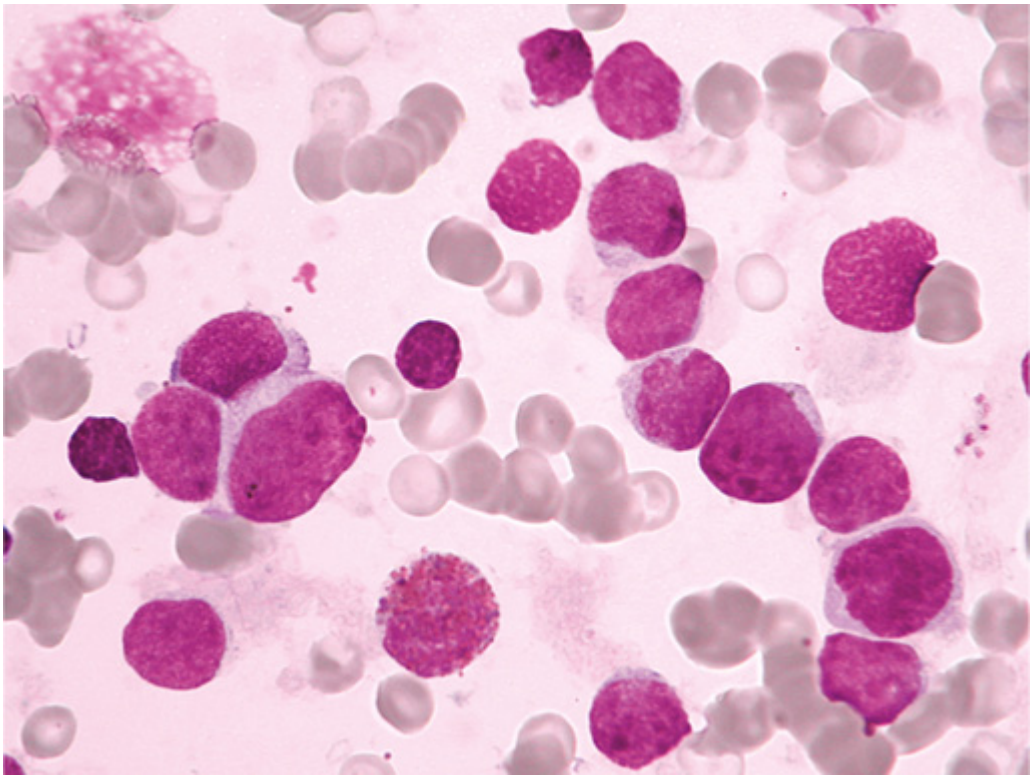

FIGURE 57-8 Neuroblastoma mimicking acute leukemia in the bone marrow aspirate; note the rare tumor cluster.

Medulloblastoma is a primitive neuroectodermal tumor of the cerebellum in children that sometimes metastasizes to the bone marrow. Advances in the underlying molecular pathogenesis have informed classification, prognostication, and targeted therapeutic approaches.[38] On histology, blastoid cells are present in sheets, often forming Homer-Wright rosettes, and sometimes present with features resembling neuroblastoma (neurofibrillary stroma and/or ganglionic differentiation). Tumors often are positive for synaptophysin and GFAP.

Primary Tumors of Bone

Ewing's Sarcoma

Ewing's sarcoma is usually primary to bone, although extraskeletal forms occur. The median age is 13 years.[39] It is one of the most undifferentiated tumors and is composed of blastoid cells with interspersed small hyperchromatic cells resembling lymphocytes (**Fig. 57-9**). Mitoses are variable, and necrosis is often present, with pseudorosettes of tumor cells surrounding necrotic centers and perivascular tumor cuffing in necrotic areas. Some tumors show neuroectodermal differentiation, though the term "primitive neuroectodermal tumor" is no longer used and tumors are classified according to molecular characteristics, with Ewing's sarcoma most commonly associated with an *EWSR1*::*FLI1* fusion.[39] The IHC profile overlaps with that of neuroblastoma. Positive markers include vimentin, NSE, synaptophysin, CD56, and FLI1.[39] MIC2 (CD99) is characteristically present in Ewing's sarcoma but must be interpreted with caution because lymphoblasts and, sometimes, myeloblasts are also positive.

Bone and Cartilage–Forming Tumors

Bone-forming tumors (osteomas, osteoid osteomas, osteoblastomas, and osteosarcomas) are characterized by the presence of osteoid. Osteosarcoma is the most common primary bone tumor, usually occurring between ages 10 and 25 years or after 40 years. The incidence is increased in older patients with Paget's disease, after radiation or alkylating agent chemotherapy, and in the setting of pre-existing bone lesions, including fibrous dysplasia, osteochondromatosis, and chondromatosis. These sarcomas show a variety of histologic appearances, including fibroblastic and

chondroblastic differentiation, but are diagnosed by the presence somewhere in the tumor of malignant osteoid formation.[40-42]

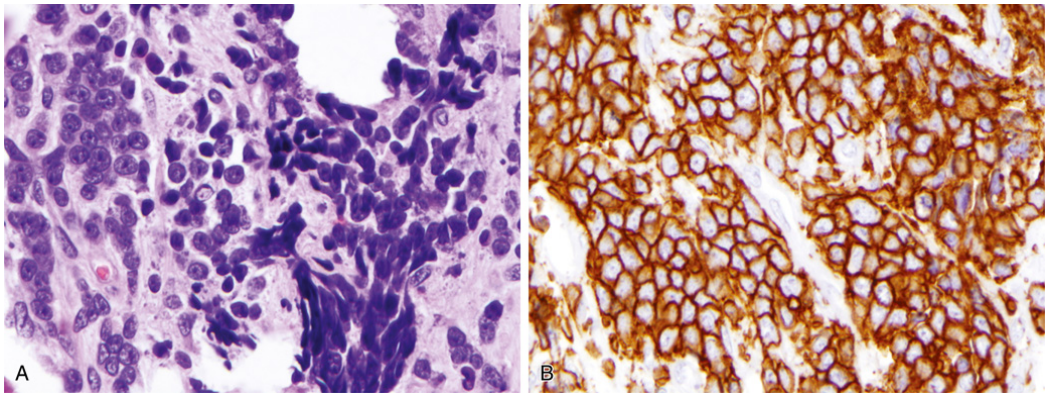

FIGURE 57-9 **A,** Appearance of Ewing's sarcoma in an H&E (hematoxylin-and-eosin)-stained bone marrow section. **B,** The same tumor expresses CD99.

Cartilage-forming tumors include benign chondromas (those originating in the diaphyses are termed *enchondromas*) composed of mature lobules of hyaline cartilage, often with myxoid degeneration, calcification, and ossification. Osteochondromas are the most common benign bone tumor and have a characteristic radiologic appearance. Chondroblastomas are cellular and may contain giant cells; chondromyxoid fibromas are also cellular benign cartilaginous tumors. Chondrosarcomas, similar to osteosarcomas, show a wide variation in differentiation and may contain bone, but they lack malignant osteoid. Giant-cell tumors (osteoclastomas) are usually low-grade malignancies occurring in the long bones or skull.

Vascular Tumors Involving Bone

Hemangiomas

Hemangiomas of bone occur principally in flat bones of the skull and jaw and in vertebrae. They are benign vascular malformations consisting of lattice-like formations of endothelial-lined cavernous spaces containing blood. Lymphangiomas occur less commonly. Massive osteolysis (Gorham's disease) appears similar to hemangioma but is destructive, leading to resorption of bone and replacement by heavily vascularized fibrous tissue.

Epithelioid Hemangioendotheliomas

Epithelioid hemangioendotheliomas show vessels lined by plump eosinophilic epithelioid or histiocyte-like endothelial cells with large vesicular nuclei and often an inflammatory infiltrate rich in eosinophils. Tumor cells show a spectrum of cytologic atypia ranging from hemangioma to angiosarcoma. Endothelial cells express CD31, CD34, and von Willebrand factor antigen. This disorder may simulate Langerhans cell histiocytosis.

Other Soft-Tissue Tumors Involving Bone

A wide variety of additional soft-tissue tumors may present in bone and include desmoplastic fibromas, fibrosarcomas, undifferentiated pleomorphic sarcoma, leiomyomas, leiomyosarcomas, lipomas and liposarcomas, chordomas, and adamantinomas. For these and for details on primary bone tumors, refer to texts on the surgical pathology of bone tumors.[40-42]

Malignant Lymphomas Involving Bone and Bone Marrow

Malignant lymphomas may occur as tumors primary in the bone or bone marrow and are discussed in detail elsewhere in this volume. Most commonly, localized bone involvement by malignant lymphoma is a result of diffuse large B-cell lymphoma (**Chapter 22**). Those occurring in the tibia of young men may be a unique favorable variant.[43] Though uncommon, precursor B-cell lymphoblastic lymphoma (**Chapter 41**) may present as a localized tumor or in the bone or skin.

Benign Lesions of Bone

Benign Tumor-like Lesions

Benign tumor-like lesions of bone include solitary and aneurysmal bone cysts and ganglion cysts.[44] Radiographic changes are often characteristic. Solitary bone cysts occur most often in the proximal metaphysis of the humerus or femur of males younger than 20 years of age and consist of a membrane of well-vascularized fibrous tissue around a fluid-filled cyst. Aneurysmal bone cysts occur mostly in adolescents in vertebrae and flat bones. An eccentrically expanded, eroding hemorrhagic mass consists of blood-filled spaces separated by fibroblasts, myofibroblasts, and histiocytes. Septa also contain blood vessels, osteoid, bone, calcifying fibromyxoid stroma, and rows of osteoclasts. Ganglion cysts occur near a joint space and contain gelatinous material lined by a thin fibrous membrane and surrounded by condensed bone.

Metaphyseal Fibrous Defect (Nonossifying Fibroma) and Fibrous Dysplasia

Metaphyseal fibrous defect, also known as nonossifying fibroma, is a storiform fibrous lesion with scattered osteoclasts and hemosiderin-laden macrophages near the epiphyses of long bones in adolescents. Fibrous dysplasia is a benign lesion that consists of fusiform expansion of the medullary space with thinning of the cortex of long or flat bones. It consists of highly cellular fibrous tissue with irregular bone formations lined by abnormal fibroblast-like osteoblasts.

Paget's Disease

Paget's disease of the bone is a relatively common disorder in older adults usually involving multiple sites (polyostotic), most often the lumbosacral spine, pelvis, and skull. Pelvic involvement makes it likely to be seen in an iliac crest bone marrow biopsy. It is initially an osteoclastic lytic lesion in which there is irregular repair leading to thickened bony trabeculae with irregular cement lines demarcating successive layers of resorption and repair. More orderly cement lines are seen in reactive situations.

Chronic Osteomyelitis

Chronic osteomyelitis is characterized by increased inflammatory neutrophils, lymphocytes, and plasma cells, often in a fibrotic background with the presence of *sequestrum* (infected dead bone) and *involucrum* (a surrounding formation of new bone). In acute osteomyelitis, pus often perforates the periosteum and forms a sinus tract to the skin. With healing, the epithelium of the sinus tract may become entrapped within the bone and form inclusion cysts or even, over time, squamous cell carcinoma.

Epithelial inclusions may also be seen as artifacts in bone marrow biopsy specimens. If the central trocar of a biopsy needle is not firmly in place when the needle is pushed through skin overlying the biopsy site, fragments of skin or other dermal or subcutaneous structures may be sampled, appearing to be entrapped within the bone marrow space in histologic sections. Contaminants from other biopsies processed concurrently may be suspected when there is space between the unexpected tissue and the marrow space. Molecular characterization of suspected “floaters” may not be possible in bone marrow specimens as a result of prior decalcification, requiring repeat sampling.

Metabolic Bone Diseases

Patients with a history of normal skeletal development but with skeletal pain or fracture and radiologic evidence of osteopenia may have metabolic bone disease. Active osteoporosis (with accelerated bone turnover) shows increased osteoid formation with increased proportion (>20%) of trabeculae showing osteoid seams of normal width. Greater than four collagen layers of lamellae are present, and trabeculae are lined by plump osteoblasts. Increased osteoclasts (>1–2 per section and/or clustered) are also present. Peritrabecular fibrous tissue (osteitis fibrosa) similar to that of hyperparathyroidism may be seen. Inactive osteoporosis (with reduced turnover) shows thin osteoid seams, flattened osteoblasts, and reduced osteoclasts. There is both formation and resorption of bone; however, overall, there is loss of bone.

Osteomalacia and rickets (vitamin D deficiency) are abnormalities of calcification. Osteomalacia is histologically difficult to identify and

may require fluorescence examination after tetracycline administration; positive results show decreased fluorescence. Rickets results in uncalcified masses of cartilage in the growth plate of a child. Hyperparathyroidism, either primary (from parathyroid adenoma) or secondary (from renal failure), results in increased osteoclastic and osteoblastic activity with peritrabecular fibrosis, known as osteitis fibrosa (**Fig. 57-10**). Scurvy (vitamin C deficiency) results in the inability to form osteoid because of abnormal collagen transformation. Calcified cartilage is seen with radiologic evidence of increased density at the growth plate.

Metastatic Tumors to Lymph Nodes

The identification of metastatic solid tumors in lymph nodes is one of the most important tasks in diagnostic surgical pathology. Up to 5% of patients with cancer present with lymph node metastasis from an occult primary tumor. Most of these neoplasms are carcinomas; however, 2% of patients with melanoma and a smaller percentage of patients with germ cell tumors and sarcomas may initially present with lymph node metastasis. This section reviews the histologic features and ancillary tests that can be performed on a metastatic tumor to identify its site of origin.

Histologic Features of Metastatic Tumors

Most solid tumors metastasize to regional lymph nodes after invasion of peritumoral lymphatics, with sequential progression down the lymphatic chain. As a result, metastatic deposits in lymph nodes are initially located preferentially in the extranodal vessels and subcapsular sinuses. This localization pattern is diagnostically useful

because it is uncommon in lymphoma, with the exception of anaplastic large-cell lymphoma. More extensive metastatic involvement is usually multifocal or geographic, but there is often a discrete boundary separating the tumor from uninvolved areas of the lymph node. Often, tumor nests or extranodal large vessel invasion in fat may be associated with a lymphoid response and mimic a lymph node, so attention to the presence of a capsule or subcapsular sinus and a circumscribed versus stellate appearance can be useful. Metastatic solid tumors usually have a cohesive appearance, forming sheets, nests, or islands, but undifferentiated carcinoma and melanoma often have a discohesive appearance, mimicking lymphoma.

Histologic clues to the site of origin of a metastatic tumor include keratinization or mucin production in carcinomas, rosette formation in neuroendocrine tumors, melanin pigment in melanomas, and abundant extracellular matrix or a fibrillary-filamentous cytoplasmic appearance in sarcomas. Metastatic papillary tumors of the thyroid gland, kidney, ovary, or lung can show nuclear pseudoinclusions and psammoma bodies; carcinomas of lung and prostate origin often show evidence of partial neuroendocrine differentiation; and foci of necrosis (often with admixed neutrophils and debris) are common in colon adenocarcinoma. Cytochemical stains for mucin, neurosecretory granules (e.g., Grimelius and Fontana), or extracellular matrix proteins (e.g., reticulin and Masson trichrome) have largely been replaced by IHC in routine diagnosis.

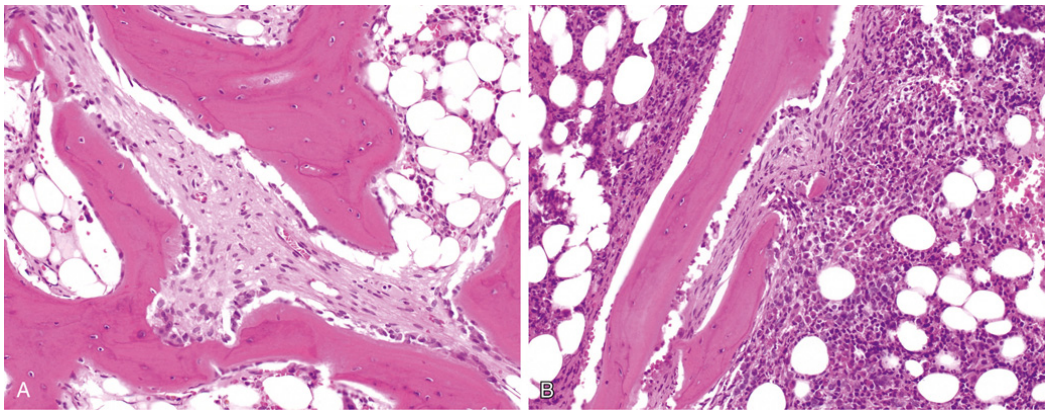

FIGURE 57-10 **A–B,** Osteitis fibrosa caused by secondary hyperparathyroidism in a patient with chronic renal insufficiency.

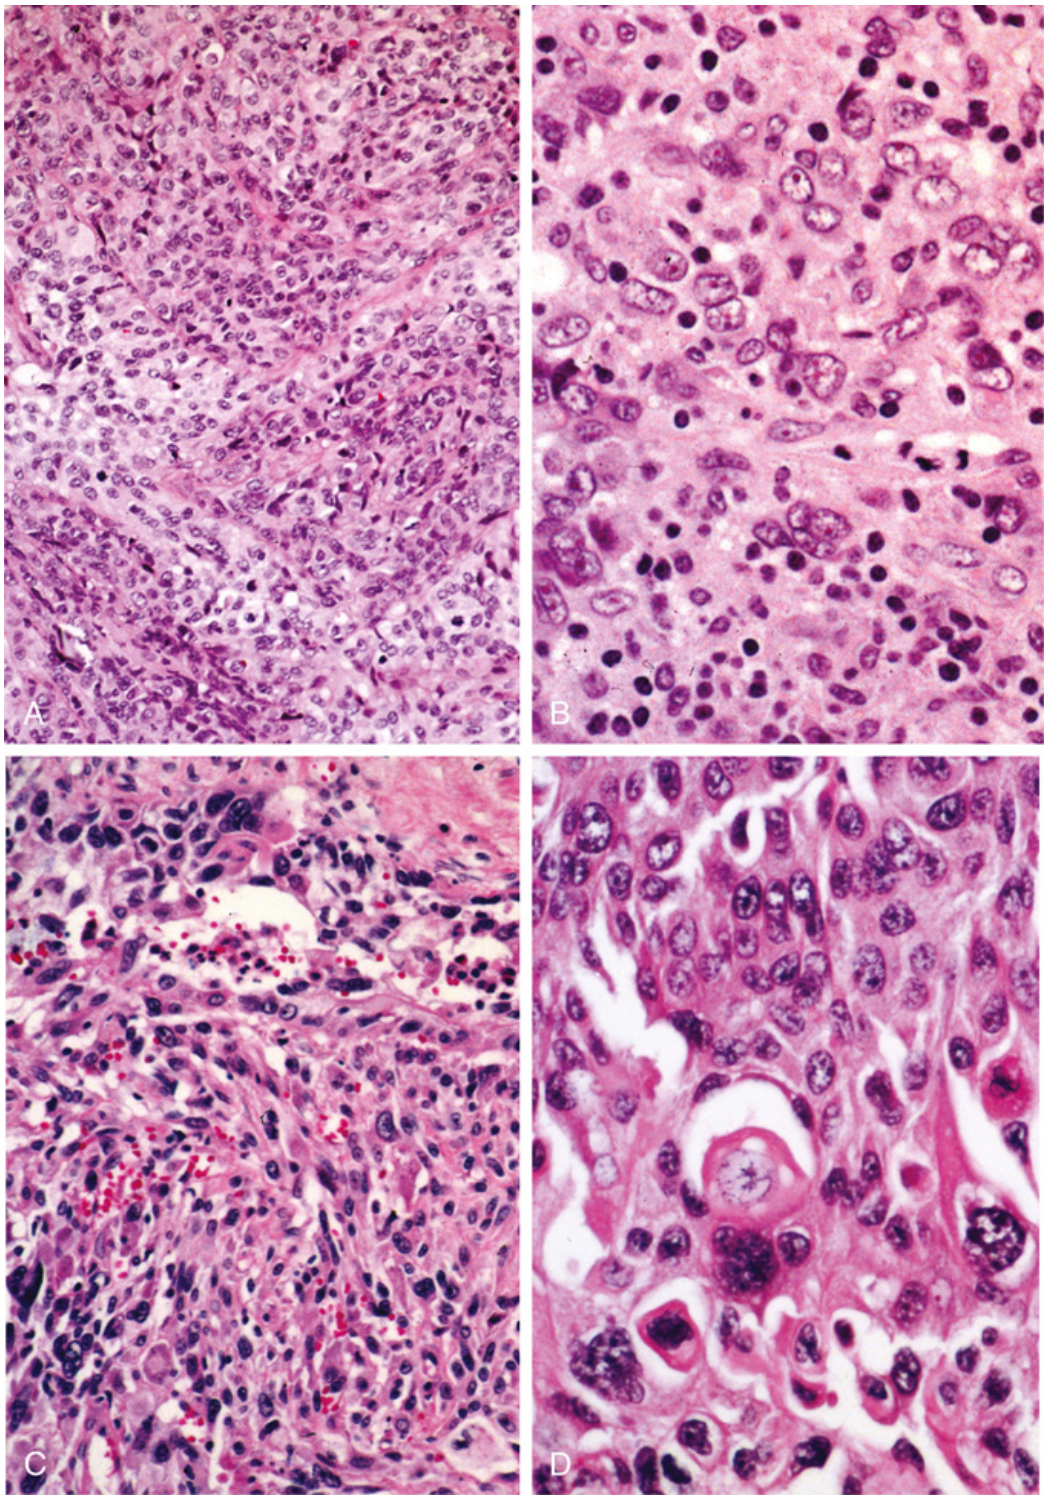

FIGURE 57-11 Histologic categories of metastatic tumor in lymph node.For the differential diagnosis to be simplified, metastatic

tumors can be divided into those that have an epithelioid **(A)**, anaplastic **(B)**, or spindled **(C)** appearance. Areas of keratinization **(D)** can be useful in identifying carcinoma. All four cases shown are metastatic carcinoma.

Poorly differentiated metastatic tumors are common and can be classified preliminarily as epithelioid, anaplastic, spindled, or small cell (**Fig. 57-11**). **Table 57-1** outlines the differential diagnosis of metastatic tumors in each of these morphologic categories. Because of their relatively small cell size and discohesive growth, small-cell tumors are among the most difficult to detect and distinguish from lymphoma; in some instances, IHC is required for diagnosis. Lobular carcinoma of the breast (**Fig. 57-12**), carcinoid tumor, small-cell carcinoma, Merkel cell carcinoma, and neuroblastoma can all show subtle infiltration of the interfollicular nodal areas. Colonization of lymphoid follicles is also occasionally observed. In the mediastinum, occult lung metastasis of small-cell carcinoma can mimic lymphoblastic lymphoma but typically shows more prominent nuclear molding. Small-cell carcinomas of the lung also commonly have abundant coagulative necrosis and basophilic deposition of DNA within blood vessels (known as nuclear encrustation or the Azzopardi phenomenon). Zonal areas of necrosis may also be seen in neuroblastoma. Although rare, rhabdomyosarcoma (**Fig. 57-13**) and Ewing's sarcoma (**Fig. 57-14**) can both show subtle interfollicular infiltration of the lymph node and should be considered in younger patients.

Among epithelioid tumors, metastatic carcinoma and melanoma are the most common non-hematopoietic tumors encountered.

Metastatic melanoma, in particular, may resemble a hematolymphoid neoplasm with immunoblastic, plasmablastic, or anaplastic morphology, including large-cell lymphoma or plasma cell myeloma (**Fig. 57-15A**). Other tumors with epithelioid morphology include metastatic seminoma (**Fig. 57-16**), especially in retroperitoneal lymph nodes, and large-cell lymphoma, cases of which may appear cohesive, particularly those with anaplastic morphology.

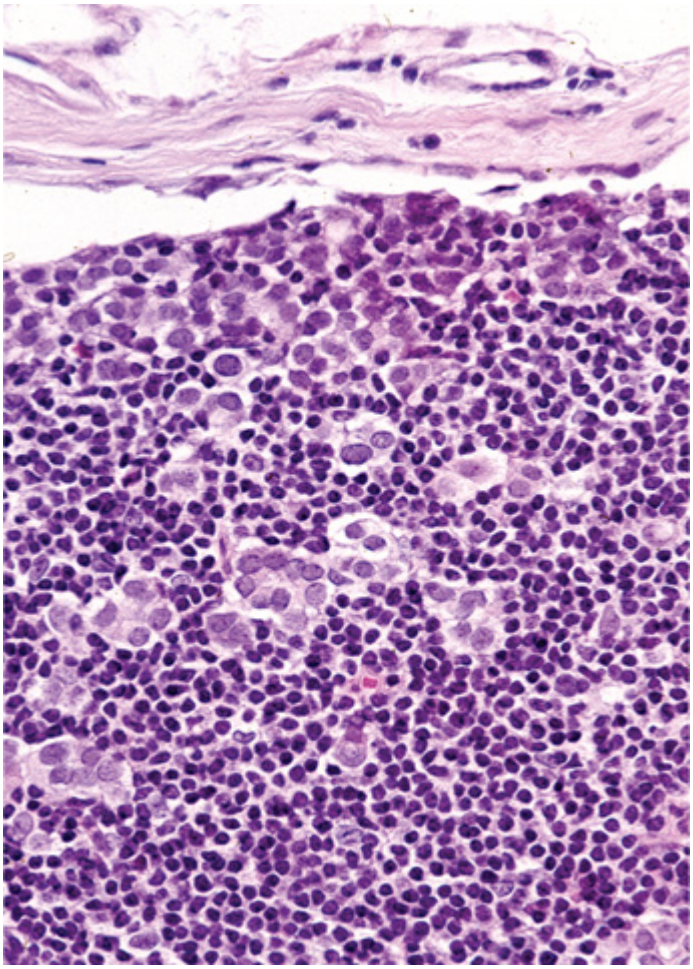

FIGURE 57-12 Metastatic lobular carcinoma of the breast.Subtle infiltration of the lymph node subcapsular sinus and paracortex by tumor cells in small nests is often observed.

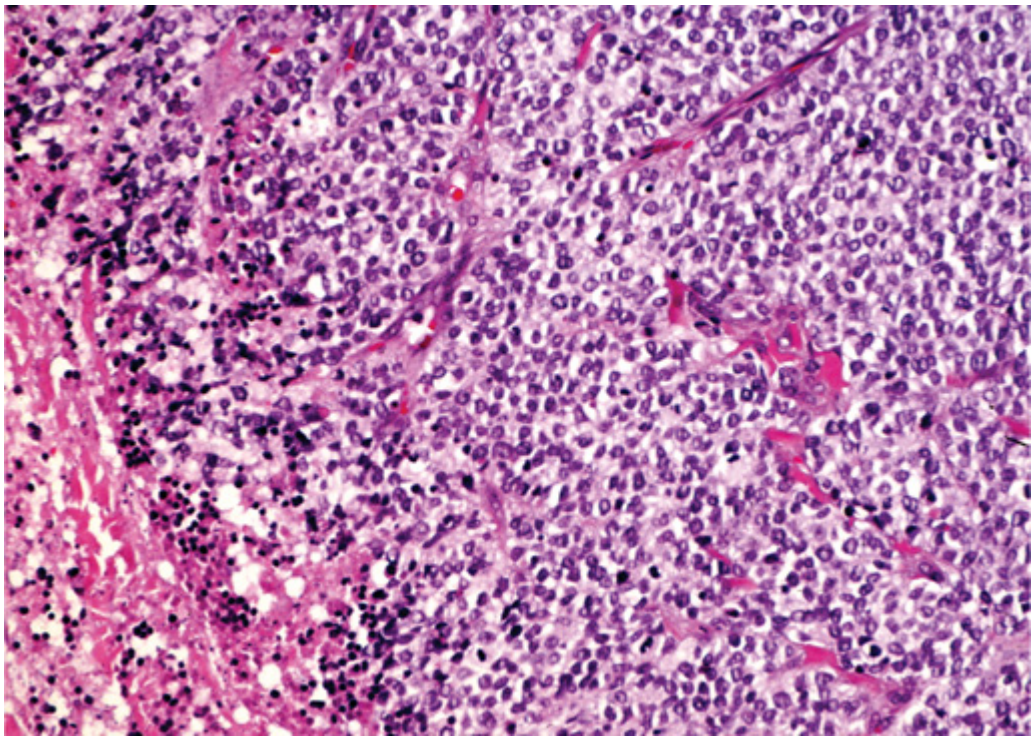

FIGURE 57-13 Metastatic rhabdomyosarcoma.Diffuse replacement of the lymph node by this small-cell neoplasm may be difficult to distinguish histologically from lymphoblastic lymphoma because diagnostic rhabdomyoblasts may be rare. A predominantly nested growth pattern can be a clue to the diagnosis.

In general, anaplastic tumors presenting in a lymph node have a broad differential diagnosis and can show abnormal antigen-expression patterns (**Fig. 57-15B–C**). Moreover, antigen shedding from infiltrating lymphoid cells or histiocytes can mistakenly make the undifferentiated tumor appear positive for hematopoietic markers. While the presence of so-called hallmark cells may suggest anaplastic large-cell lymphoma, similar cells can be seen in other

anaplastic tumors, such as anaplastic thyroid carcinoma. Careful attention to cytoplasmic features is helpful: for example, focal mucin droplets may be present in poorly differentiated adenocarcinoma and intracellular lumens may be seen in vascular tumors.

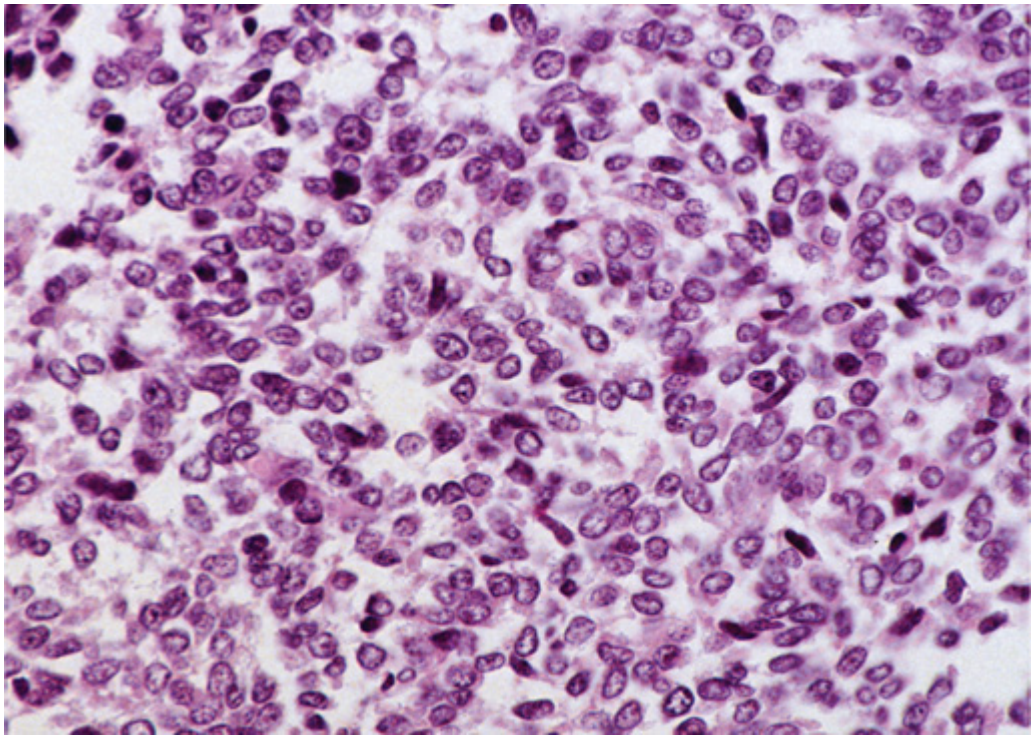

FIGURE 57-14 Metastatic Ewing's sarcoma.The fine nuclear chromatin (described as "smoky" or "dusty") of these small-cell tumors may mimic blastic hematopoietic malignancies, but they usually have more abundant cytoplasm with indistinct borders and large areas of necrosis *(not shown)*. Pseudorosette formation is usually focal or absent in lymph node metastases.

Characteristic Biological Patterns of Metastasis

In addition to histologic features and patient demographic data, the location of an involved lymph node can narrow the possible sources of a metastatic tumor. In cervical lymph nodes, the most commonly encountered occult tumor is squamous cell carcinoma or undifferentiated carcinoma from a head or neck primary tumor.[45] The primary site can be located in approximately 40% of these cases by subsequent clinical examination and is usually at the base of the tongue or tonsillar fossa. Survival is determined by the extent of lymph node involvement at presentation. Occult carcinomas originating in the lung and esophagus are the next most commonly encountered metastatic tumors in cervical lymph nodes.[46]

In patients with supraclavicular lymphadenopathy as a result of metastasis, carcinoma is the most common pathologic finding.[47] Tumors of abdominal origin preferentially result in left supraclavicular (Virchow's) lymph node enlargement, whereas tumors of the head and neck, lung, and breast (in addition to lymphomas) can involve either side.[48] Metastatic tumors in axillary lymph nodes most often originate from the breast in women,[49,50] followed in frequency by melanoma, cutaneous squamous cell carcinoma, and lung cancers. In inguinal lymph nodes, the most common metastatic tumors are melanoma and prostate carcinoma in men and gynecologic malignancies in women.[51] Germ cell tumors, mostly seminoma, can present as metastases involving retroperitoneal lymph nodes and are frequently extensively necrotic.[52]

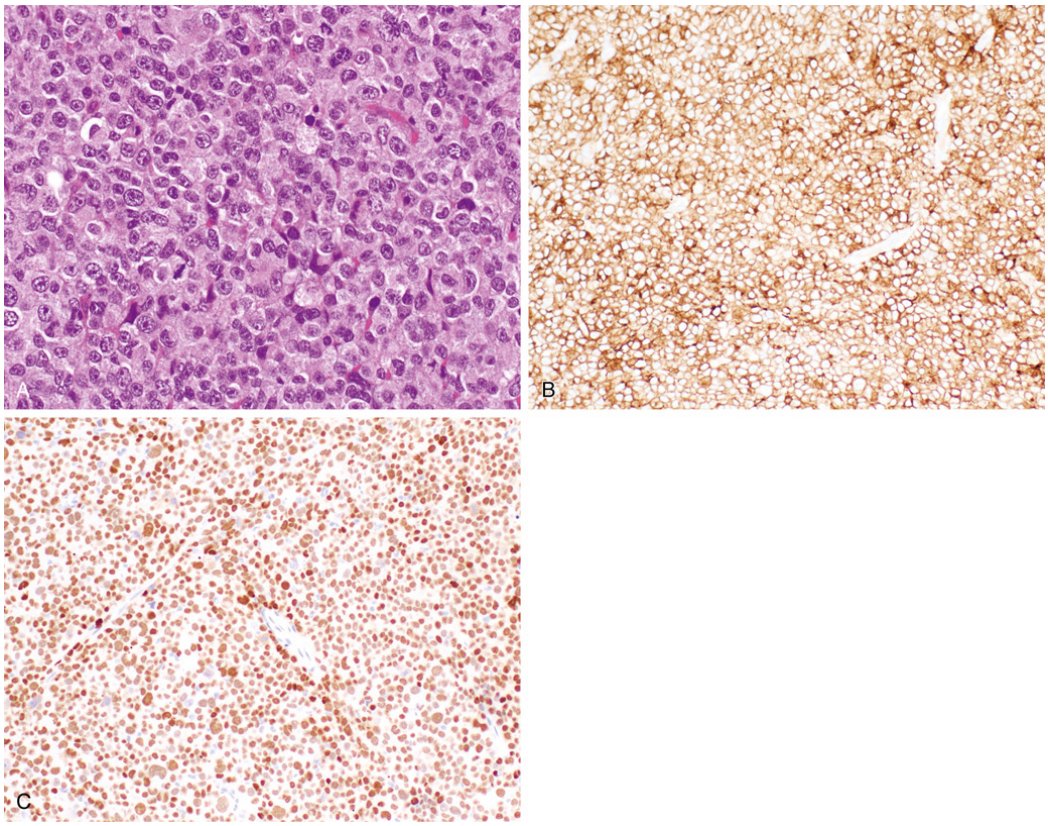

FIGURE 57-15 Metastatic melanoma.**A,** Discohesive tumor cells with eccentric nuclei, prominent nucleoli, open chromatin, and moderately abundant eosinophilic cytoplasm impart a plasmacytoid appearance, mimicking plasmablastic lymphoma. **B,** The neoplastic cells aberrantly express CD10, further raising concern for a hematopoietic neoplasm; however, B-lineage specific markers, including immunoglobin light chains, are not clearly expressed *(not shown)*. Awareness of this diagnostic pitfall prompts appropriate immunohistochemical workup with melanoma-

related stains, including SOX10 **(C)**, leading to the correct diagnosis.

Role of Immunohistochemistry in the Diagnosis of Metastatic Tumors

IHC stains for metastatic tumors are divided into those used for diagnosis and those used for prognostic or treatment purposes. A review of the prognostic markers is beyond the scope of this chapter, and they are constantly evolving. Suggested diagnostic IHC panels for different tumor categories are shown in **Table 57-2**.

In general, the commonly used first-tier diagnostic antibodies are highly specific but variably sensitive for the detection of particular tumor types.[53] However, aberrant or unrecognized patterns of staining with routine antibodies must always be considered. Most hematopoietic markers in common use are specific for hematopoietic cells, but some hematopoietic markers, such as CD5, CD7, CD10, CD43, CD56, and CD138/syndecan-1, are commonly expressed in neuroendocrine tumors or carcinomas from certain sites.[54-56] Also, CD30 is strongly expressed by embryonal germ cell tumors and sometimes by mesotheliomas,[57] and CD45 (leukocyte common antigen [LCA]) may be positive in the cytoplasm of breast carcinoma with rare membranous positivity in poorly differentiated carcinomas.[58] Conversely, S-100 protein and the vascular marker CD31 are variably expressed by monocytes and macrophages. VS38, CD138/syndecan-1, and CD38 are plasma cell markers. However, VS38 and CD138/syndecan-1 are expressed by many solid tumors,[59] whereas CD38 is more restricted to plasma cells and some lymphocytes and histiocytes. Finally, plasmacytomas are notorious

for aberrant and false-positive immunoreactivity and can stain for cytokeratin, myeloperoxidase, and T-cell markers, among others.[60]

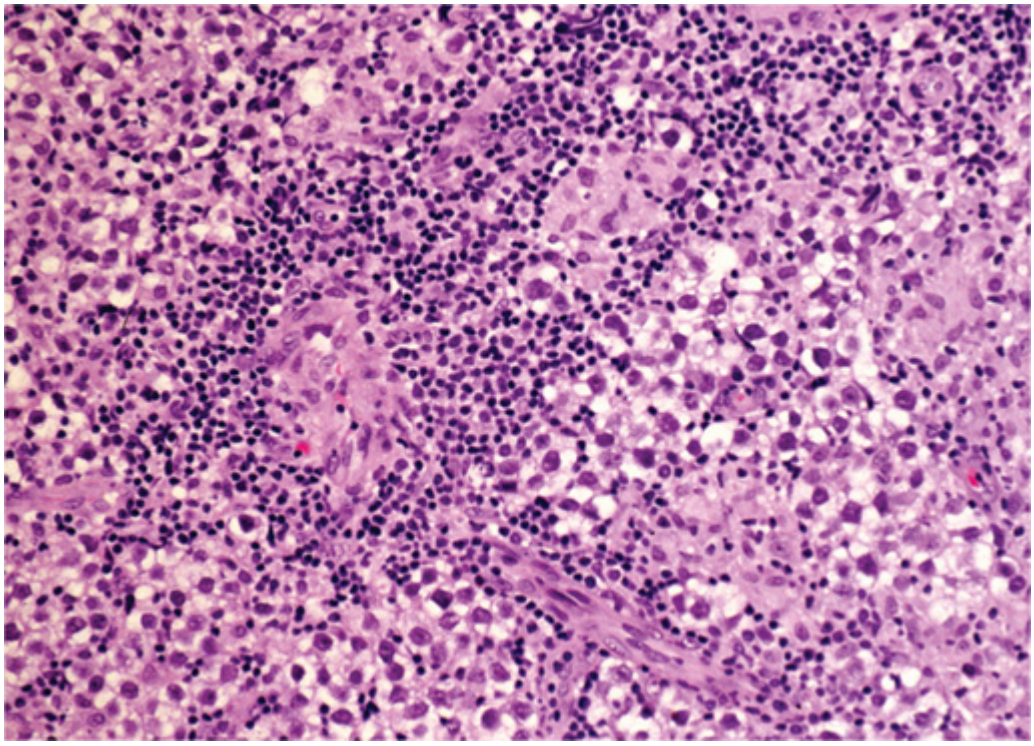

FIGURE 57-16 Seminoma metastatic to lymph node.The lymph node is infiltrated by large germ cells with abundant clear cytoplasm and distinct cell borders. A helpful feature in distinguishing metastatic seminoma from large-cell lymphoma is the admixed granulomatous reaction and small lymphocytes.

In metastatic carcinoma of unknown origin, a second group of immunohistochemical stains can complement the histologic appearance and clinical data, suggesting a possible primary site.[61] Currently, the most broadly useful antibodies are those that detect the cytokeratin expression pattern, particularly keratin 7 and keratin

20 (**Fig. 57-17**).[62,63] The overall patterns of these markers are summarized in **Table 57-3**, but it is important to note that variations may be seen among the more poorly differentiated tumors. Other markers can be helpful in identifying metastasis from less common primary sites. For example, hepatocellular carcinoma is typically negative for keratin 19 (in contrast to cholangiocarcinoma) but positive for low–molecular-weight keratin, as detected by CAM5.2.[64] The pattern of keratin positivity can also be helpful. A punctate or dotlike paranuclear cytoplasmic staining pattern is characteristically observed in Merkel cell carcinoma and small-cell carcinoma but not completely specific for these tumor types. It should be noted that some lymphomas (approximately 2%) of both mature and lymphoblastic types can show some keratin positivity, most commonly keratin 8.[65,66]

Table 57-2

Routine Immunohistochemistry Panels for Diagnosis

Histologic Group	First Round of Staining	Second and Third Rounds of Staining
Small-cell tumors	Pan-keratin, TdT, LCA, desmin	Chromogranin, synaptophysin, CD56, CD34, CD99, NKX2.2, lymphoid markers, myogenin, myo-D1, calcitonin
Anaplastic and epithelioid tumors	Pan-keratin, S-100, CD30, LCA	EMA, PLAP, immunoglobulins, SOX10, HMB45, melan A, CD68, myeloperoxidase
Spindle cell tumors	Smooth muscle actin, desmin, S-100, pan-keratin	HHF35 actin, CD117/KIT, LCA, caldesmon, CD21, CD23, or CD35 (follicular dendritic cell sarcoma)

EMA, Epithelial membrane antigen; *FDC,* follicular dendritic cell; *LCA,* leukocyte common antigen; *PLAP,* placental alkaline phosphatase; *TdT,* terminal deoxynucleotidyl transferase.

The complex pattern of IHC expression of the classic serum tumor markers, including CEA, CA19-9, CA15-3, CA125, EMA/MUC1, β-human chorionic gonadotropin, and α fetoprotein, limits their role as

diagnostic markers except in particular cases (e.g., canalicular CEA staining detected by polyclonal antiserum in hepatocellular carcinoma).[54,67] Similarly, polypeptide hormones and their receptors, such as testosterone, estrogen, and progesterone receptors, can be expressed by a wide variety of carcinomas and should be used cautiously as evidence of a particular cell lineage.

Molecular profiling with a limited array of transcripts of lineage-associated genes has shown great promise in accurate classification[68-70] and the selection of appropriate therapies.[71] Cytogenetic analysis, although technically demanding, can be highly useful in evaluating the poorly differentiated blastoid tumors; there are characteristic translocations that support the diagnosis of lymphoblastic lymphoma, neuroblastoma, rhabdomyosarcoma, Ewing's sarcoma, and other sarcoma types. Targeted FISH analysis for specific chromosomal translocations can routinely be performed on cytologic smears and touch imprints with high sensitivity. Although less sensitive, FISH is also frequently done on fixed, paraffin-embedded tissue sections. Next-generation sequencing (NGS)-based approaches on DNA extracted from paraffin-embedded tissue are increasingly being used to identify fusion proteins characteristic of certain tumors, even when only one gene partner is known.[72] Electron microscopy has a limited role in the differential diagnosis but can be helpful in the definitive diagnosis of poorly differentiated tumors, for example, by detecting melanosomes in poorly differentiated melanoma or cell junctions that would suggest a carcinoma or dendritic cell neoplasm. In small-cell tumors, electron microscopy is especially useful in detecting muscle filaments in rhabdomyosarcoma. Multigene expression profiling assays can be

used to identify tumors of uncertain origin using reverse transcription polymerase chain reaction (RT-PCR) for detecting mRNA or microRNA from frozen or paraffin tissue samples and are reported to have high diagnostic accuracy.[73-76]

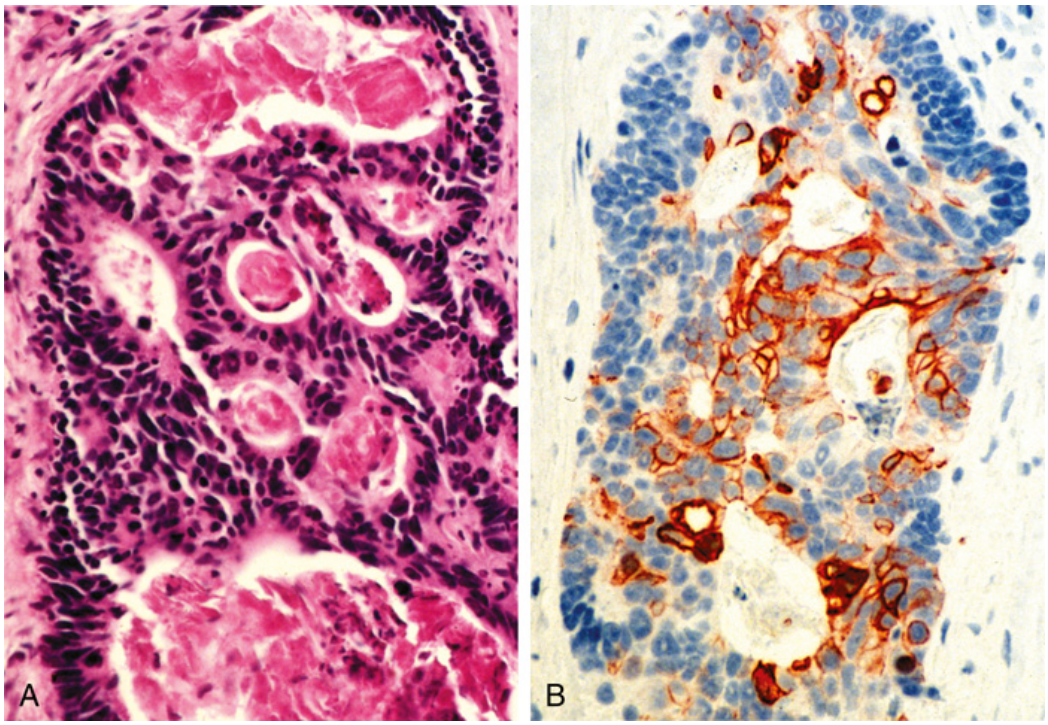

FIGURE 57-17 Keratin immunostaining of colon adenocarcinoma metastatic to lymph node.**A,** Columnar tumor cells that replace the nodal parenchyma exhibit gland formation with central necrosis, typical of colon adenocarcinoma. **B,** Tumor cells are positive for cytokeratin 20 but negative for cytokeratin 7 *(not shown)*.

Table 57-3

Immunohistochemical Stains Used to Identify the Site of Origin of Metastatic Carcinoma

Marker	Specificity
Arginase	Liver
β-catenin	GI tract, ovarian
CDX2	GI tract
Calcitonin	Medullary thyroid carcinoma; rarely, other neuroendocrine tumors
Chromogranin	Neuroendocrine differentiation, including small-cell and Merkel cell carcinomas
Cytokeratin 7^+, 20^-	Lung, breast, transitional cell, endometrioid ovarian, some neuroendocrine and squamous cell carcinomas
Cytokeratin 7^-, 20^+	GI tract, mucinous ovarian, Merkel cell
Cytokeratin 7^+, 20^+	Transitional cell (bladder), cholangiocarcinoma
Cytokeratin 7^-, 20^-	Adrenocortical, hepatocellular, prostate, renal cell, small-cell carcinoma, squamous cell (esophageal), carcinoid, germ cell tumor

Marker	Specificity
Fli-1	Ewing's sarcoma, vascular tumors
GATA3	Breast, salivary gland, urothelial tumors
GCDFP-15	Breast, salivary gland, some prostate tumors
HepPar1	Hepatocellular carcinoma, small subset (~5%) of other adenocarcinomas and neuroendocrine tumors
HMB45	Melanoma, lymphangioleiomyomatosis
Mammaglobin	Breast carcinoma, endometrial adenocarcinoma
MART-1/melan A	Melanoma, adrenocortical carcinoma, other steroid-producing tumors
Myogenin, MyoD1	Rhabdomyosarcoma
Napsin A	Lung adenocarcinoma, papillary renal cell carcinoma
Oct-4	Seminoma and embryonal carcinomas of testis
P63 and/or p40	Squamous cell carcinoma, urothelial carcinoma
PAP	Prostate, some carcinoids, apocrine breast and salivary tumors

Marker	Specificity
PAX8	Endometrial adenocarcinoma, ovarian serous, renal cell carcinoma, thyroid carcinomas
PLAP	Germ cell tumors; occasional carcinomas of lung, GI, and Müllerian origin; some histiocytes
Podoplanin/D2-40	Kaposi sarcoma, some angiosarcomas, lymphangioma
PSA	Prostate carcinoma (decreased in poorly differentiated tumors), some breast carcinomas
pVHL	Renal clear cells in addition to clear cells of ovary and uterus
RCC	Renal cell carcinomas
Surfactant A	Lung adenocarcinomas
Synaptophysin	Neuroendocrine differentiation, including neuroblastoma, medulloblastoma, small-cell and Merkel cell carcinomas
Thyroglobulin	Thyroid tumors (not anaplastic or mucoepidermoid)
TTF-1	Lung and thyroid carcinomas and neuroendocrine tumors at these sites

Marker	Specificity
Villin	GI tumors (brush border–type staining)
Vimentin	Negative in endometrial and low-grade renal carcinomas, positive in most other carcinomas

GCDFP, Gross cystic disease fluid protein; *GI,* gastrointestinal; *PAP,* prostatic acid phosphatase; *PLAP,* placental alkaline phosphatase; *PSA,* prostate-specific antigen; *TTF-1,* thyroid transcription factor-1.

Nonlymphoid Tumors With Prominent Reactive Lymphoid Components

In several neoplasms, the density of tumor-associated reactive lymphocytes can obscure the tumor cells. This is particularly common in seminoma, melanoma, and medullary carcinoma of the breast. In mediastinal biopsy specimens, thymoma should always be a diagnostic consideration when numerous small lymphocytes are associated with an epithelioid or spindle cell proliferation. The diagnosis of thymoma can be further complicated by the immature thymic immunophenotype of the reactive T-cell component, which can be indistinguishable from T-lymphoblastic lymphoma by flow-cytometric analysis. In such cases, IHC can easily detect the extensive cytokeratin-positive tumor meshwork.

Undifferentiated nasopharyngeal carcinoma (or undifferentiated carcinoma arising from other sites, such as urothelial tumors) is probably the solid tumor most frequently misdiagnosed as lymphoma.[77] This is because of its occasionally prominent inflammatory component and the fact that occult nodal

presentations of nasopharyngeal carcinoma are common, occurring in up to 50% of cases. The keratinizing and nonkeratinizing squamous cell variants of nasopharyngeal carcinoma usually present few diagnostic difficulties (**Fig. 57-18**). However, in the lymphoepithelioma variant of undifferentiated nasopharyngeal carcinoma (also known as the Schmincke type), the neoplastic cells are often obscured by a dense lymphocyte infiltrate (**Fig. 57-19**). Other cases can be associated with numerous neutrophils and eosinophils and may mimic Hodgkin lymphoma (**Fig. 57-20**). Tumor cell cohesiveness and central necrosis within tumor cell aggregates are helpful clues. The most useful ancillary tests for the diagnosis of nasopharyngeal and undifferentiated carcinomas are keratin IHC and Epstein-Barr virus–encoded small RNA (EBER) in situ hybridization.

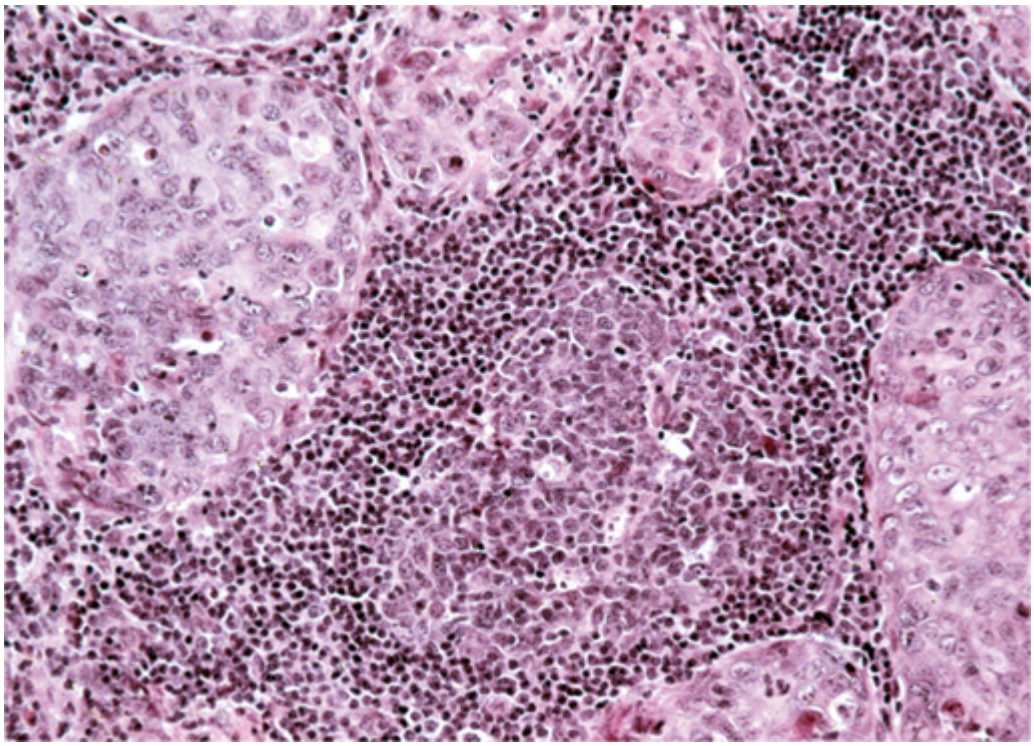

FIGURE 57-18 Metastatic nonkeratinizing squamous cell carcinoma of nasopharyngeal origin.Large nests of cohesive tumor cells are outlined by collagen bands and show multifocal nodal infiltration. In this field, a central reactive lymphoid follicle is surrounded by tumor.

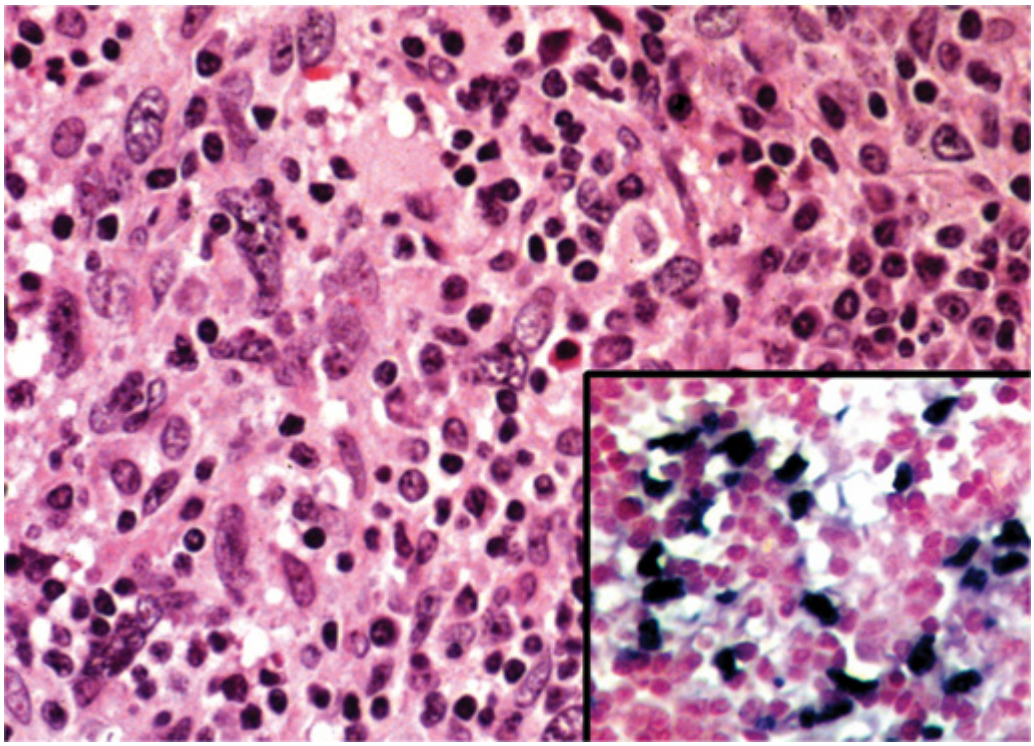

FIGURE 57-19 Metastatic undifferentiated nasopharyngeal carcinoma—Schmincke or lymphoepithelioma type.Anaplastic tumor cells are interspersed between numerous small lymphocytes. Keratin immunohistochemical stain and Epstein-Barr virus in situ hybridization *(inset)* were positive in tumor cells.

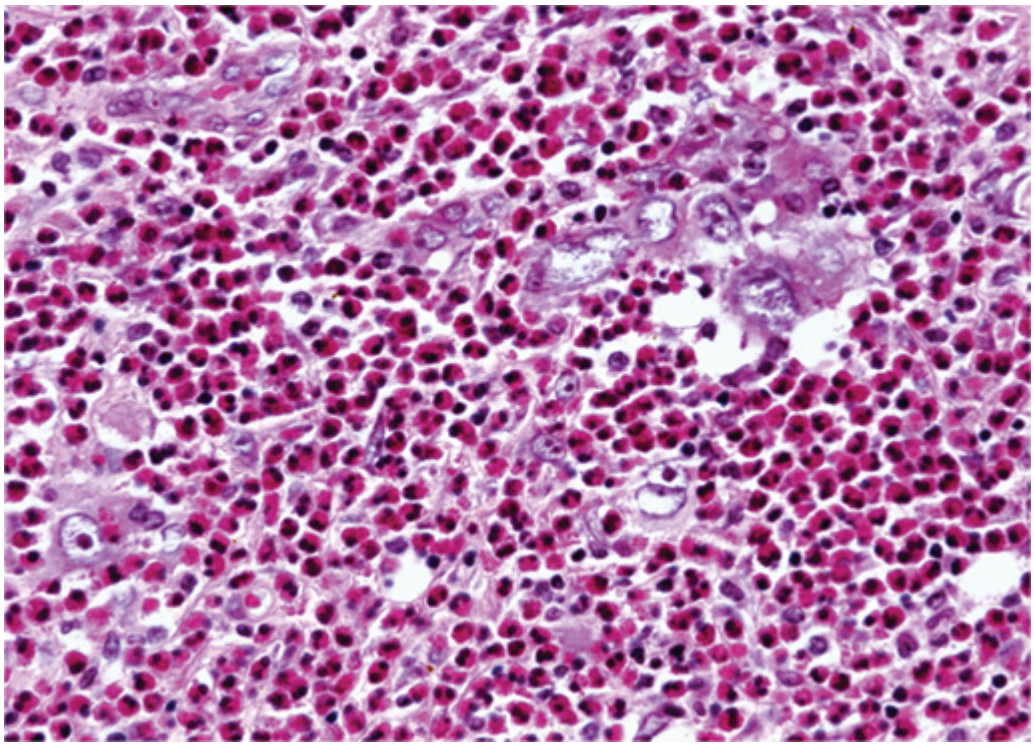

FIGURE 57-20 Metastatic undifferentiated nasopharyngeal carcinoma—eosinophil-rich variant.Large neoplastic tumor cells are interspersed between numerous eosinophils.

Benign Lymph Node Inclusions

Epithelial and Mesothelial Inclusions in Lymph Nodes

Müllerian inclusion cysts (MICs) are by far the most commonly encountered benign glandular inclusions, identified in up to 20% of lymph nodes excised from women. Such cysts may rarely be seen in men. Rare cases of florid MICs causing significant lymph node enlargement or ureteric obstruction have been reported.[78] MICs are most frequently located in the paraaortic lymph nodes and, less

frequently, in the iliac lymph nodes. Inclusions have been reported in distant nodes such as axillary lymph nodes and can mimic breast cancer.[79,80] PAX8 IHC can be useful in the diagnosis of Müllerian epithelium but does not distinguish benign from malignant inclusions.[81] MICs are usually simple cysts lined by serous-type (Müllerian) cuboidal to columnar epithelium that is cytologically bland (**Fig. 57-21**).[82] Histologic features distinguishing benign MICs from metastatic tumor deposits include an intertrabecular location in a lymph node, the presence of multiple types of benign lining cells, the lack of mitoses or cellular atypia, the presence of a periglandular basement membrane, and the absence of a desmoplastic stromal reaction. The increased incidence of MICs in patients with borderline ovarian tumors suggests neoplastic potential for benign-appearing MICs in rare cases.[83] IHC may be helpful in cases that architecturally resemble metastatic gynecologic cancers in that MICs are usually negative for CEA.[82]

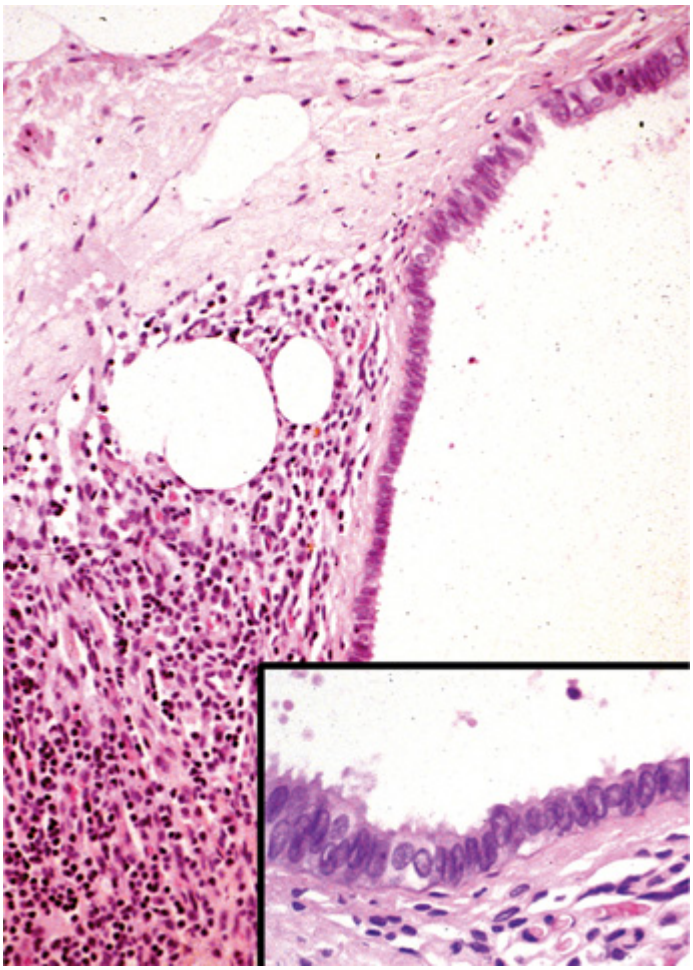

FIGURE 57-21 Endosalpingiosis of lymph node.A simple cyst in a subcapsular location, lined by cytologically bland cuboid and ciliated columnar epithelium *(inset)*.

Endometriosis in lymph nodes is usually seen only in patients with extensive peritoneal deposits; it shows benign-appearing glands with columnar epithelium, edematous endometrial-type stroma, and hemosiderin-laden macrophages (siderophages), as at other sites.[84] Estrogen and progesterone receptors and PAX8 staining can be detected by IHC.[81] Endosalpingiosis with associated psammoma bodies has been rarely reported in lymph nodes.

Benign epithelial inclusions resembling glands from nearly all solid organs have been reported in adjacent lymph nodes. Apparent neoplastic transformation of such benign inclusions has also been rarely reported.[85] Given the close proximity of many lymph nodes to the salivary glands, it is not surprising that these nodal groups often contain numerous salivary ducts and glands. In dense lymphoepithelial lesions of the salivary gland (e.g., lymphoepithelial cysts, acquired immunodeficiency syndrome [AIDS]-associated sialoadenitis, Sjögren syndrome), it may be difficult to distinguish salivary gland tissue from the adjacent lymph node. Salivary gland neoplasms, including Warthin's tumor and pleomorphic adenoma, have been reported to arise from heterotopic salivary gland ducts within lymph nodes. Similar collections of benign ducts and glands can be observed in perithyroidal, axillary, and perirenal lymph nodes. Rarely, squamous-type inclusion cysts may be identified in lymph nodes; clinical and radiologic correlation is necessary to exclude metastatic squamous cell carcinoma with cystic changes (**Fig. 57-22**).

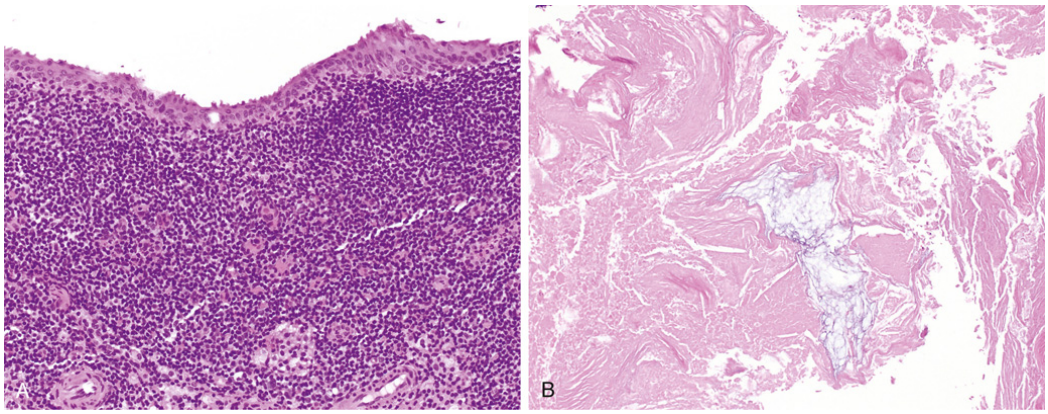

FIGURE 57-22 Nodal squamous-type inclusion cyst.**A,** An axillary lymph node core biopsy shows benign lymphoid tissue adjacent to a cyst wall composed of stratified squamous epithelium. **B,** Detached fragments of keratin debris are seen, consistent with cyst contents.

Bland but occasionally enlarged mesothelial cells can occur as detached groups within the lymph node sinuses, usually in the mediastinum and rarely at other sites.[86] Lymph node sinus mesothelial cells are often increased and can be numerous after chest compression. These keratin-positive mesothelial inclusions are most problematic in crushed and fragmented mediastinal lymph node biopsy specimens obtained for the diagnosis of suspected malignancy. IHC positivity for mesothelial cell markers (e.g., calretinin, HMBE-1) and the absence of staining for pan-epithelial markers (e.g., Ber-EP4) can be helpful in problematic cases.

Keratin-Positive Fibroblastic Reticular Cells

In interpreting lymph node IHC, it is important to recognize that the fibroblastic reticular cell network can be variably positive for keratin. Fibroblastic reticular cells, usually identified by antibodies that

detect keratins 8 and 18 (e.g., CAM5.2), have a spindled or dendritic morphology and usually present few diagnostic difficulties in tissue sections. However, their presence in cytologic preparations may be more confusing. In some reactive lymph node expansions, keratin-positive fibroblastic reticular cells may be quite numerous but still maintain their dispersed pattern of infiltration (**Fig. 57-23**). A rare sarcoma derived from these cells, termed *cytokeratin-positive interstitial reticulin cell (CIRC) sarcoma,* can easily be confused for metastatic carcinoma; these tumors stain for keratins 8 and 18, vimentin, and smooth muscle actin.

Nevus Cell Aggregates

Nevus cell aggregates are most commonly seen in axillary lymph node dissection specimens, where they may be mistaken for carcinoma, melanoma, and cervical and inguinal lymph nodes; nevus cell aggregates are rare in deep lymph nodes.[87] Nevus cells are present much more frequently in staging lymph nodes from patients with melanoma (up to 25%) than in lymph nodes excised for other reasons.[88] This finding, in addition to the increased frequency of nodal nevus aggregates in patients with congenital nevi, suggests aberrant developmental migration patterns of melanocytes in patients who subsequently develop melanocytic neoplasms.[89]

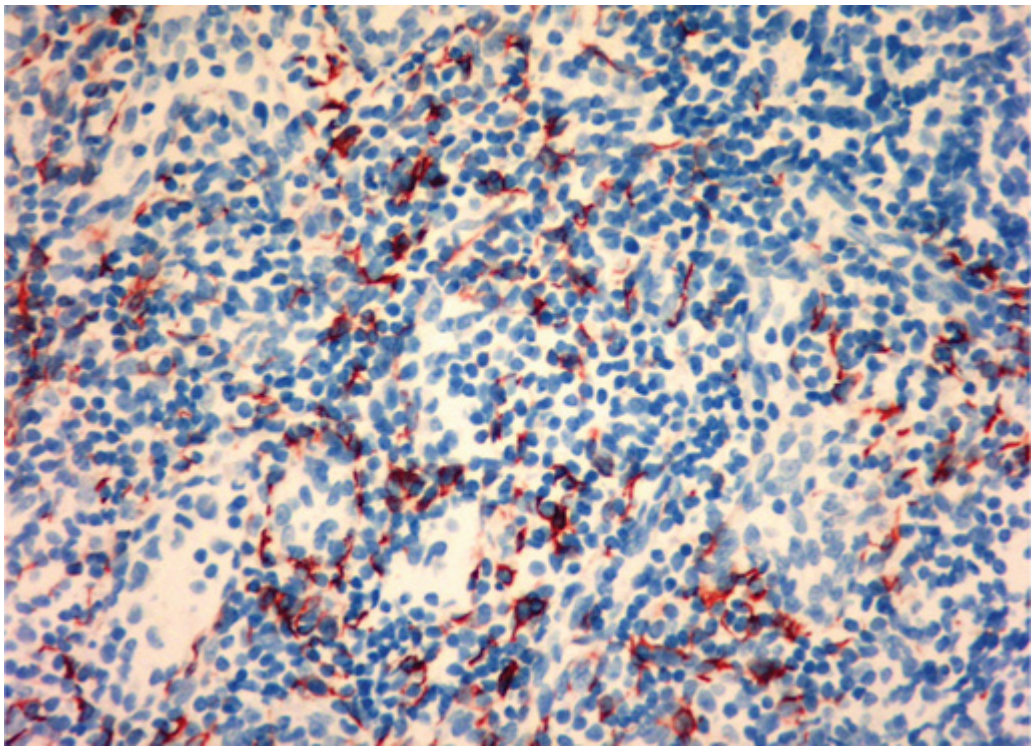

FIGURE 57-23 Keratin-positive fibroblastic reticular cells in lymph node.Cytologically benign nodal reticular cells with fine cytoplasmic cell processes are interspersed between lymphocytes (pan-keratin immunostain). Keratin-positive stromal cells are more commonly detected with low–molecular-weight keratin immunostains (e.g., CAM5.2) but may be seen with any cytokeratin antibody.

Nevus cell aggregates are most commonly embedded in the collagen of the lymph node capsule or trabeculae but can also be found within the subcapsular sinus or rarely in the lymphatics or surrounding small intranodal vessels.[88] These aggregates are usually composed of small, uniform melanocytes that resemble those seen in intradermal melanocytic nevi (**Fig. 57-24**). When melanin pigment

is inconspicuous, IHC for S-100 protein or MART-1 can be used to confirm their identity; these aggregates are often negative for HMB-45, a useful marker in the differential diagnosis.[89] In addition, neural stem cell markers, Nestin and SOX2, are useful in distinguishing nodal melanocytic nevi from metastatic melanoma, which expresses one or both markers, in contrast to nodal nevi.[90]

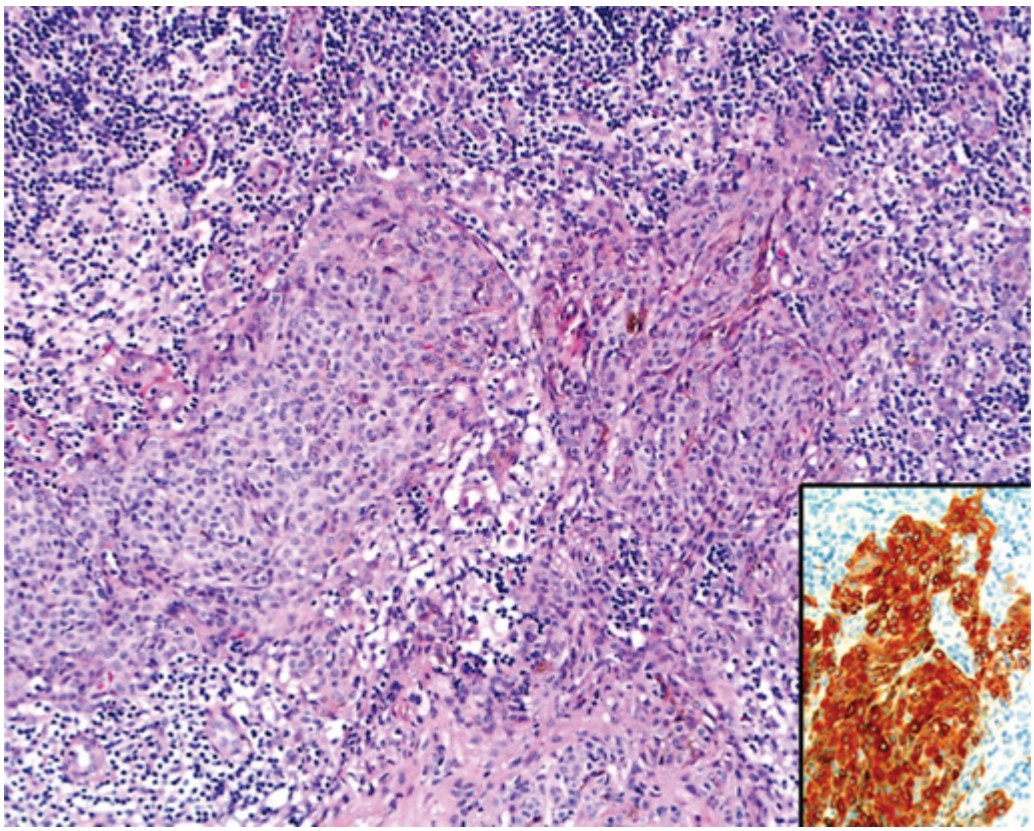

FIGURE 57-24 Nevus aggregates in lymph node.Variably pigmented nevus cells extend from lymph node trabeculae. MART-1 immunostain is diffusely positive *(inset)*. Courtesy Dr. Victor Prieto.

Lymph node metastasis from blue nevi and other cytologically bland melanocytic proliferations has been reported.[91] Clues to this occurrence would be more widespread intranodal distribution of nevus cells than commonly seen in benign nevus cell aggregates. Correlation with the presence of a large nevus in the area of the draining lymph node can help support a definitive diagnosis. The rarely reported primary nodal blue nevus usually represents similar capsular collections of spindle cells with abundant melanin pigment.[92]

Mesenchymal Proliferations in Lymph Nodes

A helpful and sensible approach to diagnosing stromal proliferations in lymph nodes is to identify the primary proliferating cell types. Benign proliferations of stroma intrinsic to the lymph node can arise from lymphatic vessels, blood vessels, fibroblastic stroma, dendritic cell types (covered in **Chapter 52**), or a combination of these types. In addition, the lymph node proliferation can be part of a (syndromic or sporadic) systemic mesenchymal disorder such as lymphangioleiomyomatosis or angiomatosis. Finally, both primary nodal sarcomas and metastatic sarcomas of all types must be considered.

Vascular Transformation of Lymph Node Sinuses and Lymphatic Proliferations

Vascular transformation of lymph node sinuses is probably the most commonly encountered reactive stromal lesion of lymph nodes. The overall architecture is preserved, but the lymph node sinuses are

prominent and show complex anastomosing channels that may contain blood cells or fibrin or have a fibrotic appearance (**Fig. 57-25**). Some cases also show solid areas that resemble hemangiomas; others show mixed solid and sinusoidal, multinodular, and even plexiform patterns. Rare cases may involve the obliteration of sinuses by a proliferation of cytologically bland, plump fibroblasts and histiocytoid cells.[93] In some cases, the proliferation raises the possibility of Kaposi sarcoma, which can be distinguished by IHC for human herpesvirus-8/Kaposi sarcoma herpesvirus (HHV-8/KSHV) latency-associated nuclear antigen-1 (LANA-1).

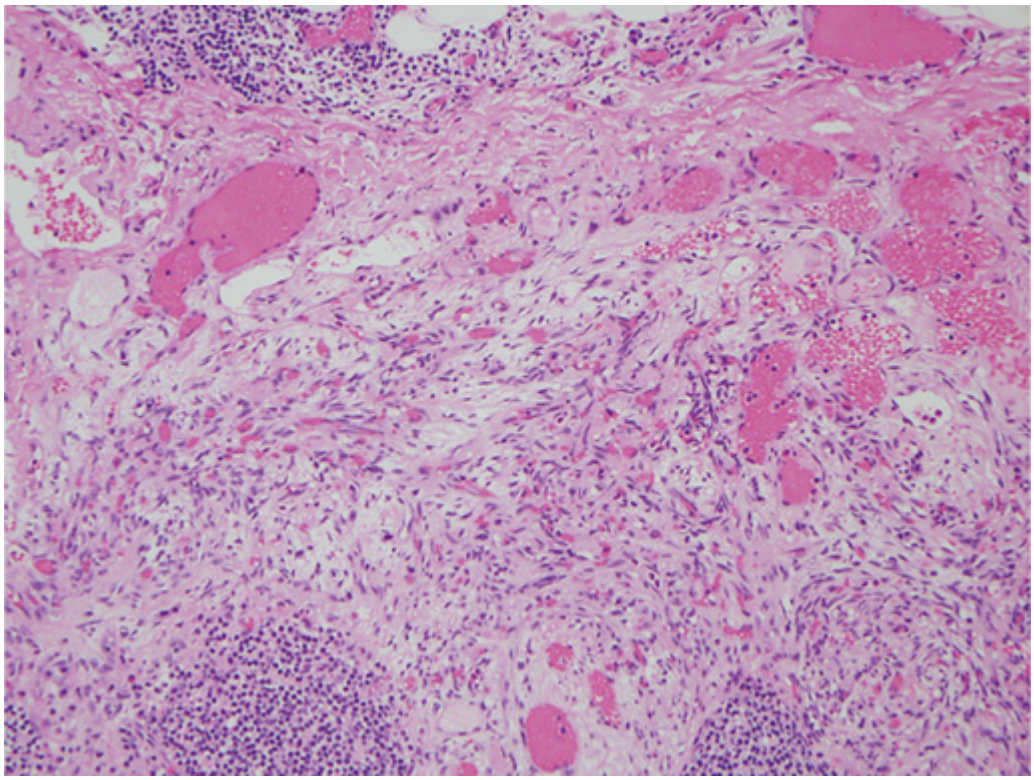

FIGURE 57-25 Vascular transformation of lymph node sinuses.Dilated sinuses show a proliferation of medium-sized and small-sized vascular spaces with red blood cells.

Vascular transformation of lymph node sinuses likely results from the effects of altered lymph flow caused by pressure changes or stasis secondary to venous or sinus obstruction.[94] Thus, it is common in lymph nodes compressed by adjacent solid tumors or in damaged lymphatic beds after surgery. The association of vascular transformation of lymph node sinuses and concurrent hemangiomas also suggests a role for angiogenic factors in inducing lymphatic proliferation or expansion. Similarly, vascular transformation–like changes can be seen in lymph node–draining lymphomas or inflammatory conditions that produce abundant cytokines.

In contrast, lymphangioma of lymph nodes is a proliferation of greatly distended, thin-walled lymphatic vessels with dense fibrotic stroma, resembling the cystic hygroma of infancy. In these benign proliferations, variably sized lymphatic spaces, filled with proteinaceous fluid and occasional lymphocytes, displace the normal nodal architecture and extend outside the lymph node.[95]

Mixed Smooth Muscle–Vascular Proliferations

Benign smooth muscle proliferations in lymph nodes are common and appear to be related to extrinsic effects; they occur most often in pelvic, inguinal, and abdominal sites, where gravitational effects on vascular or lymphatic drainage may contribute to their development. These cytologically bland lesions, which radiate out from the lymph node hilum, have been diagnosed as angiomyomatous hamartoma in cases with a mixed proliferation of smooth muscle and blood vessels (**Fig. 57-26**) in sclerotic stroma[96,97] or as leiomyomatous hamartoma when the smooth muscle component is more prominent.[97] Stromal cells in both these lesions are variably positive for smooth muscle actin, desmin, and vimentin but are negative for HMB-45. A variant of the lesion may have admixed lobules of adipose tissue and has been termed *angiomyolipomatous hamartoma of lymph node*.[98]

Palisaded myofibroblastoma (also known as hemorrhagic spindle cell tumor with amianthoid fibers) is a similar benign fibromuscular proliferation largely restricted to the pelvic lymph nodes.[99,100] These tumors are well demarcated and composed of a fascicular proliferation of spindle cells with focal nuclear palisading and acellular stellate or occasionally calcified or ossified amianthoid

collagen fibers (**Fig. 57-27A–B**). Thick-walled blood vessels and peripherally located hemorrhagic areas are admixed. Immunoreactivity for vimentin, α–smooth muscle actin (**Fig. 57-27C**), and muscle-specific actin (detected by the HHF35 antibody) and electron microscopic studies showing intracytoplasmic bundles of microfilaments support smooth muscle cell differentiation.[101] The differential diagnosis of this tumor includes schwannoma, which may contain similar amianthoid collagen but shows more prominent nuclear palisading and is positive for S-100.

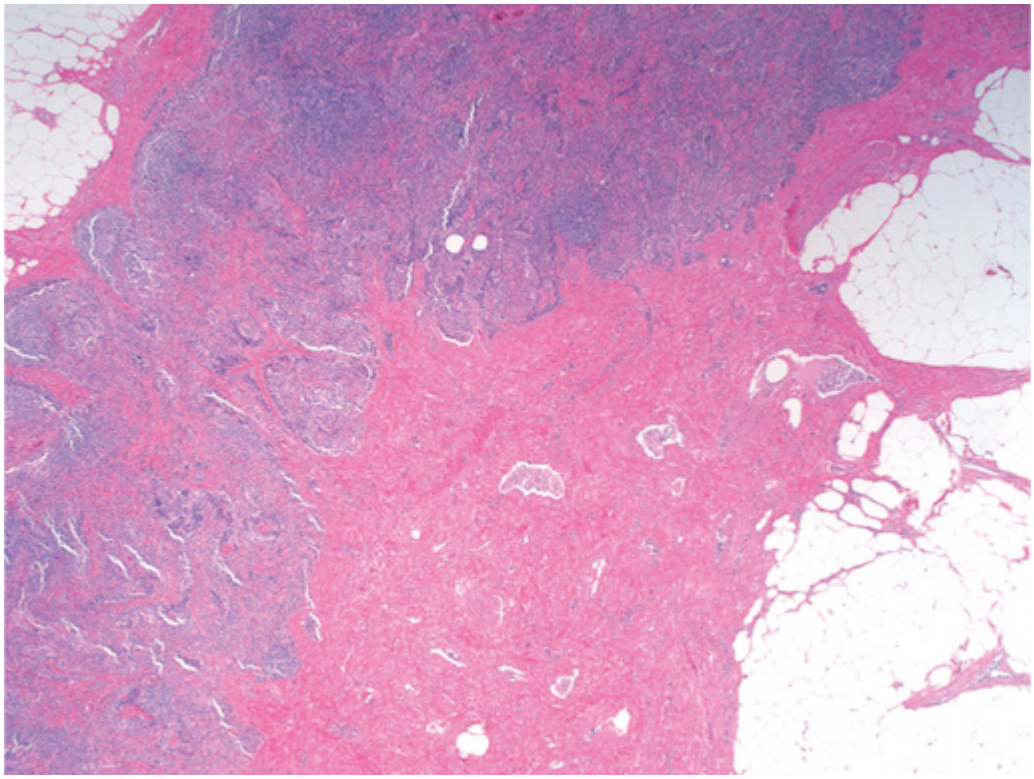

FIGURE 57-26 Angiomyomatous hamartoma of lymph node.A proliferation of smooth muscle with some large vessels fills the hilum and radiates into the lymph node cortex.

Lymphangioleiomyomatosis is a systemic proliferation of abnormal smooth muscle and malformed blood vessels and lymphatics occurring in young women. This lesion, which is linked to inactivation of *TSC2,* can occur in association with tuberous sclerosis or sporadically in patients who may also have angiomyolipomas of the kidney. The primary site of disease is usually the lung, but lymph nodes are typically involved as well. Diagnosis is aided by the presence of HMB-45–positive plump smooth muscle proliferations underlying the anastomosing lymphovascular spaces.[102,103]

Inflammatory Pseudotumor of Lymph Nodes

Dense fibroblastic or myofibroblastic proliferations in lymph nodes have been variably diagnosed as inflammatory pseudotumor. The pathologic spectrum and cause of these changes have not been firmly established and are likely to be a reaction to a variety of processes or stimuli. Patients with inflammatory pseudotumor can have marked lymph node enlargement and prominent constitutional symptoms, and surgical resection usually leads to a dramatic resolution of symptoms.[104]

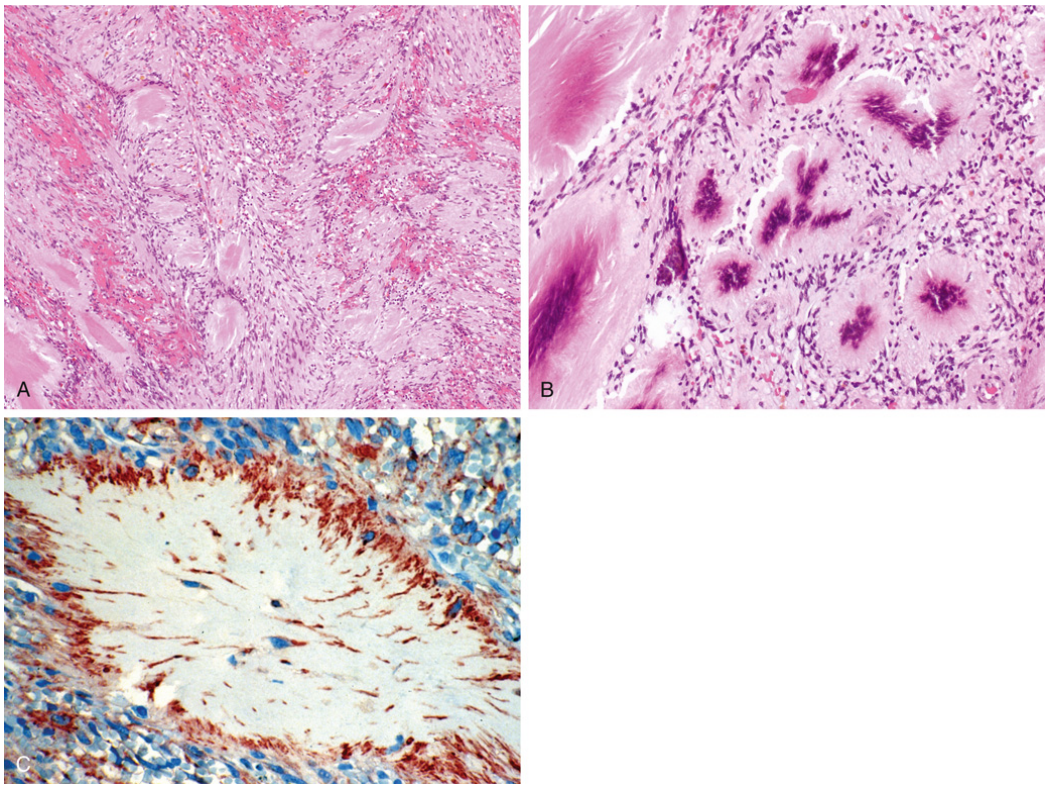

FIGURE 57-27 Palisaded myofibroblastoma.**A,** Stellate spindle cell proliferations radiate out from dense eosinophilic, sclerotic amianthoid collagen, some of which shows calcification **(B)**. **C,** There is focal smooth muscle actin expression. C courtesy Dr. Mario Luna.

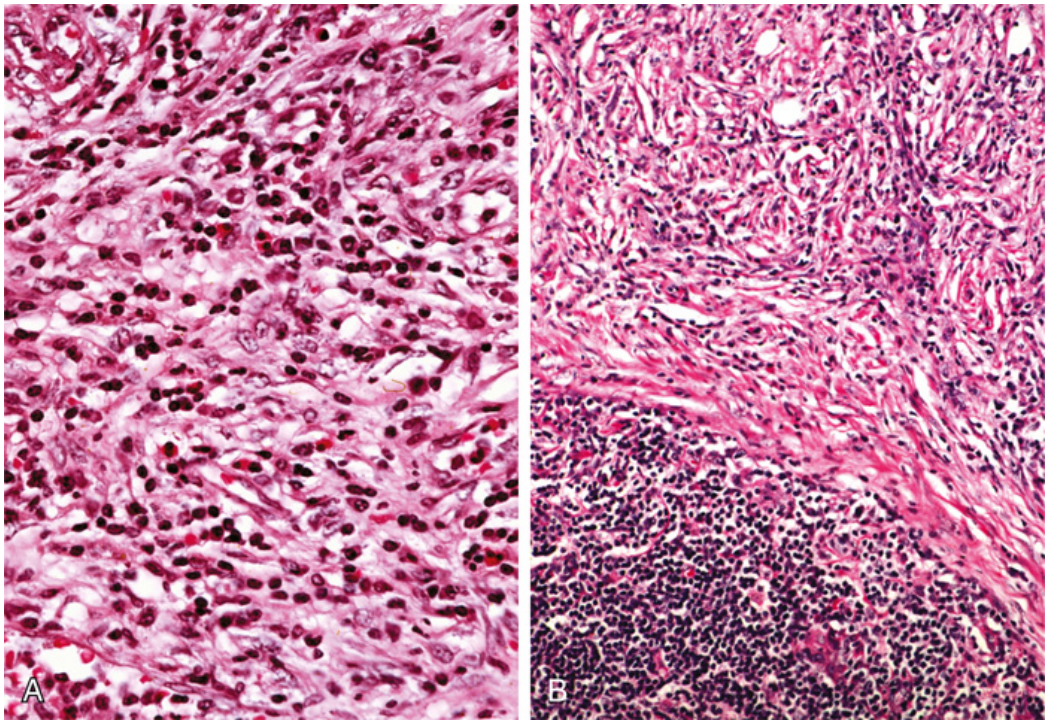

FIGURE 57-28 Inflammatory pseudotumor of lymph node.Various patterns have been described, including lesions rich in inflammatory cells **(A)** and other cellular or spindled lesions **(B)**. Differential diagnosis of the more cellular lesions includes myofibroblastic sarcoma, and underlying infection or IgG4-related disease should be excluded in lesions rich in inflammatory cells.

Inflammatory pseudotumor initially involves the paracortical areas and often the fibrous trabeculae of the lymph node, secondarily spreading into follicles and perinodal adipose tissue. Some cases are composed of a polymorphic infiltrate of acute or chronic inflammatory cells embedded in collagen-rich fibroblastic stroma (**Fig. 57-28A**). Other cases are composed of a dense, storiform

proliferation of myofibroblasts (**Fig. 57-28B**). Unlike inflammatory pseudotumors of the liver or spleen, nodal cases are negative for Epstein-Barr virus.[105]

The diagnosis of inflammatory pseudotumor requires exclusion of entities in its differential diagnosis, which is broad and includes inflammatory myofibroblastic tumor; follicular dendritic cell sarcoma; lymphoproliferative disorders associated with a fibrohistiocytic response, including Hodgkin lymphoma and T-cell lymphomas; IgG4-related disease; and infectious lymphadenitis caused by mycobacteria, spirochetes, or fungi. Workup using ancillary histochemical and IHC studies may be helpful in this regard, including stains for microorganisms, Hodgkin/Reed-Sternberg cells, CD138 or IgG and IgG4, and follicular dendritic cell antigens. One study found evidence of luetic infection in four of nine cases of nodal inflammatory pseudotumor.[106] In contrast to some cases of inflammatory myofibroblastic tumor, inflammatory pseudotumors are negative for ALK by IHC.[105]

Kaposi Sarcoma

Kaposi sarcoma is a virally induced tumor characterized by a proliferation of vascular elements and stromal cells with variable myofibroblastic differentiation. It occurs in a variety of clinical settings, including immunosuppression (solid organ transplantation, human immunodeficiency virus [HIV] infection) and older age, particularly older adult patients who are living or have lived in Mediterranean or sub-Saharan African regions where HHV-8/KSHV is endemic. Epidemic variants of Kaposi sarcoma may also occur in these regions of the world, with a much younger age of onset.

Kaposi sarcoma often extends from the lymph node capsule along the fibrous trabeculae before completely replacing the nodal parenchyma. On histology, it is composed of curvilinear fascicles of bland-appearing spindle cells with characteristic cytoplasmic periodic acid-Schiff–positive hyaline globules (**Fig. 57-29A–B**) and admixed plasma cells, hemosiderin, and extravasated erythrocytes. In the less cellular areas, sieve-like vasoformative structures are easier to appreciate. Rare cases may show sinusoidal infiltration extending throughout the interfollicular areas in a pattern resembling vascular transformation of lymph node sinuses.

The pathogenetic role of HHV-8/KSHV in Kaposi sarcoma is now well established. IHC for HHV-8/KSHV LANA-1 is useful in confirming the diagnosis (**Fig. 57-29C**). Furthermore, Kaposi sarcoma may be found in lymph nodes adjacent to the regressed follicles of HHV-8/KSHV-associated multicentric Castleman disease.

Vascular Tumors

Benign hemangiomas of lymph nodes can show the full range of histologic variants seen at other anatomic sites. They are often centered in the hilum or medulla but can also completely efface the parenchyma. The most common types in lymph nodes are lobulated capillary hemangioma with myxoid stroma and cavernous hemangioma (**Fig. 57-30**). Cases of nodal cellular hemangioma have also been described. Rarely, lesions resembling epithelioid hemangioma or angiolymphoid hyperplasia with eosinophilia can be seen in lymph nodes.

Epithelioid hemangioendothelioma, which usually occurs in lymph nodes as a metastatic tumor, is characterized by sheets, nodules, or

cords of plump, eosinophilic, vacuolated cells with small intracytoplasmic lumens that sometimes contain red blood cells in an abundant extracellular hyaline matrix (**Fig. 57-31**). The tumor cells are positive for vascular markers, including CD31 and factor VIII–associated protein. In nodal lesions of epithelioid hemangioendothelioma, central necrosis and dense fibrosis are frequently seen. Spindle cell hemangioendothelioma can be the sole histologic pattern but is more commonly a minor component of epithelioid hemangioendothelioma (**Fig. 57-32**).[107]

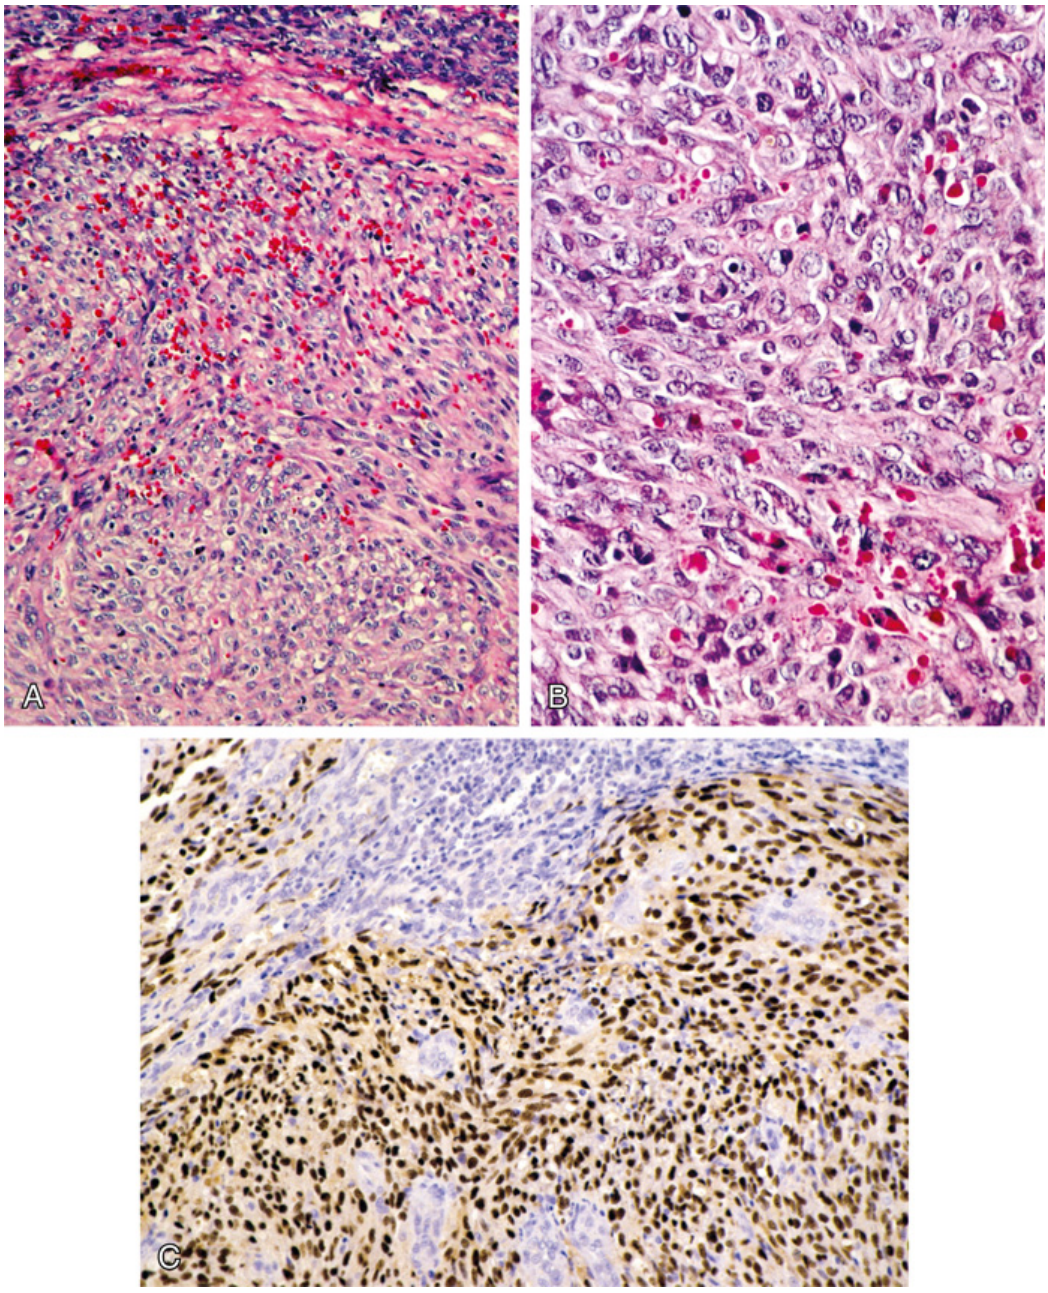

FIGURE 57-29 Kaposi sarcoma of lymph node.**A,** Hypervascular spindle cell and epithelioid cell proliferation centered on the lymph node capsule. **B,** Entrapped red blood cells and extracellular hyaline globules are diagnostic clues. **C,** IHC for human herpesvirus-8 (HHV-8)

or Kaposi sarcoma herpesvirus (KSHV) LANA-1
is diffusely positive in proliferating spindle cells.

Nodal angiosarcoma appears to be an exceedingly rare primary neoplasm, but metastasis to lymph nodes from an occult tumor can occur. Angiosarcoma is distinguished from the lower-grade vascular tumors by marked atypia, a high mitotic rate, and multilayering of tumor cells in the vasoformative areas. Tumors can have a spindled, epithelioid, or anastomosing pattern or a mixture of all patterns (**Fig. 57-33**). Epithelioid angiosarcoma is more common in retroperitoneal lymph nodes (**Fig. 57-34**).

Metastatic Sarcomas of Other Types

Primary nodal sarcomas of follicular dendritic cell, interdigitating dendritic cell, and fibroblastic reticular cell origins are described in **Chapter 52** and are not discussed here.

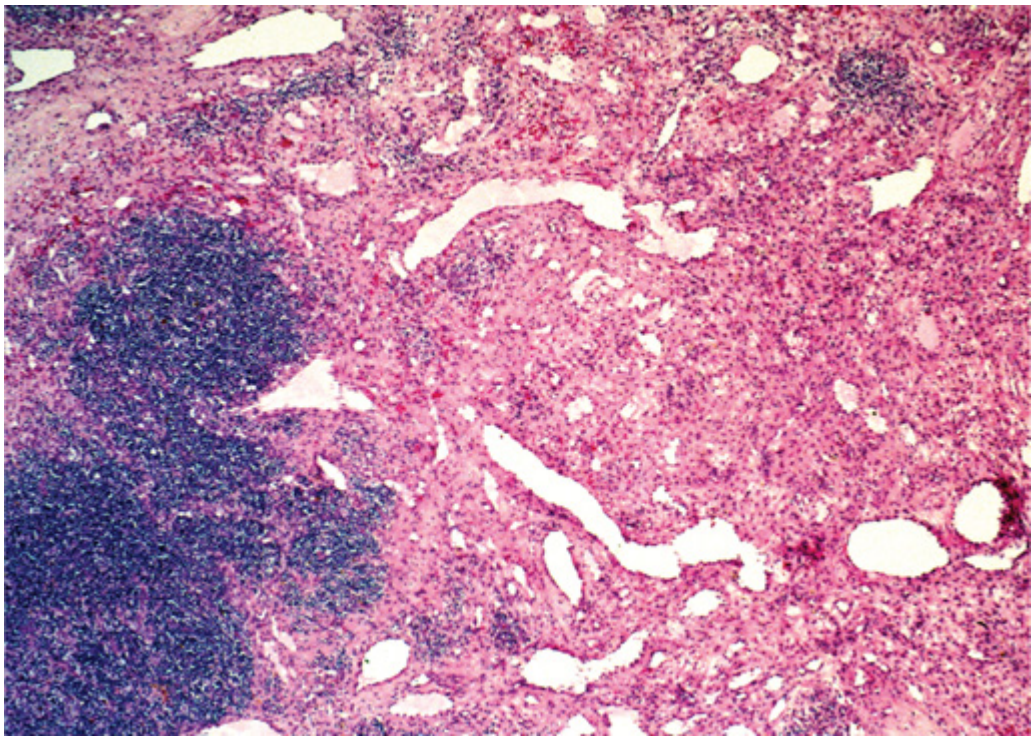

FIGURE 57-30 Hemangioma of lymph node.The nodal parenchyma is displaced by a proliferation of benign-appearing blood vessels of various sizes and dense sclerosis.

Although any histologic type of sarcoma can metastasize to lymph nodes, different sarcomas have different frequencies of lymph node metastasis. Among adult soft-tissue sarcomas, lymph node metastases are most common with rhabdomyosarcoma, angiosarcoma, and hemangioendothelioma.[108,109] Liposarcomas rarely metastasize to lymph nodes. However, inflammatory liposarcomas can mimic lymphoma or dendritic cell neoplasms, and IHC for MDM2 and CDK4 should be performed in challenging cases. Among childhood sarcomas, rhabdomyosarcoma and Ewing's sarcoma most frequently metastasize to lymph nodes, with a 10% to 15% incidence over the course of the disease.[110]

Ganglioneuroblastoma may metastasize to lymph nodes, particularly in the mediastinum (**Fig. 57-35**). Among bone tumors, both chondrosarcoma and osteosarcoma can metastasize to regional lymph nodes.

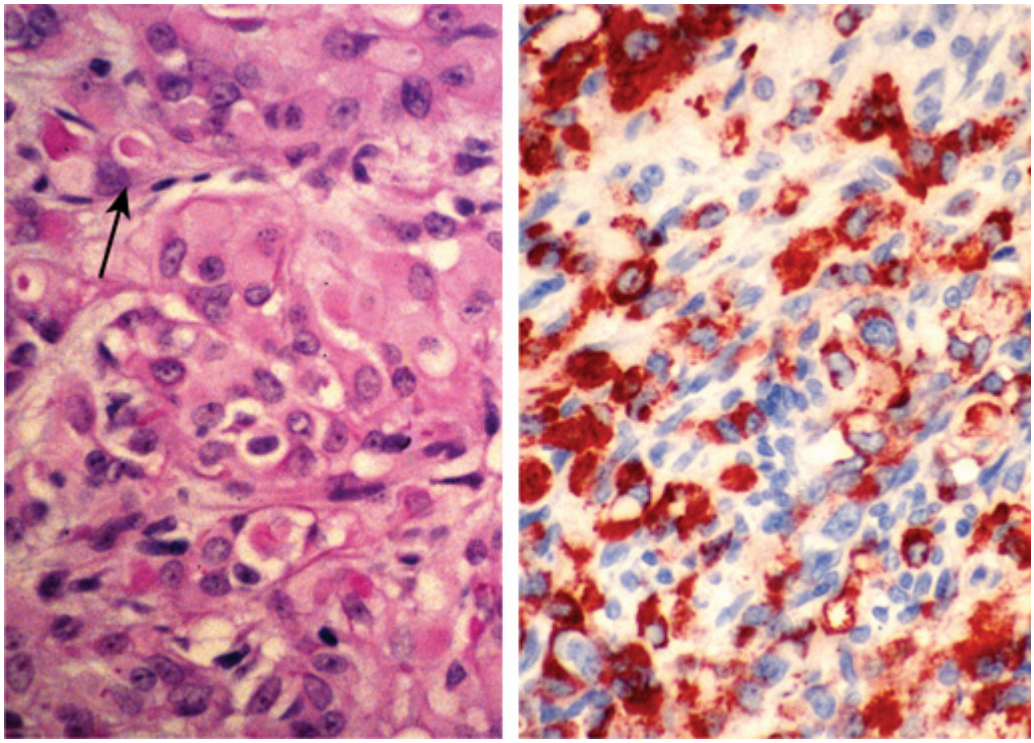

FIGURE 57-31 Epithelioid hemangioendothelioma involving lymph node.Large epithelioid cells with abundant pink cytoplasm show intracytoplasmic vacuolation *(left, arrow)*. Factor VIII–associated protein immunostain is positive *(right)*.

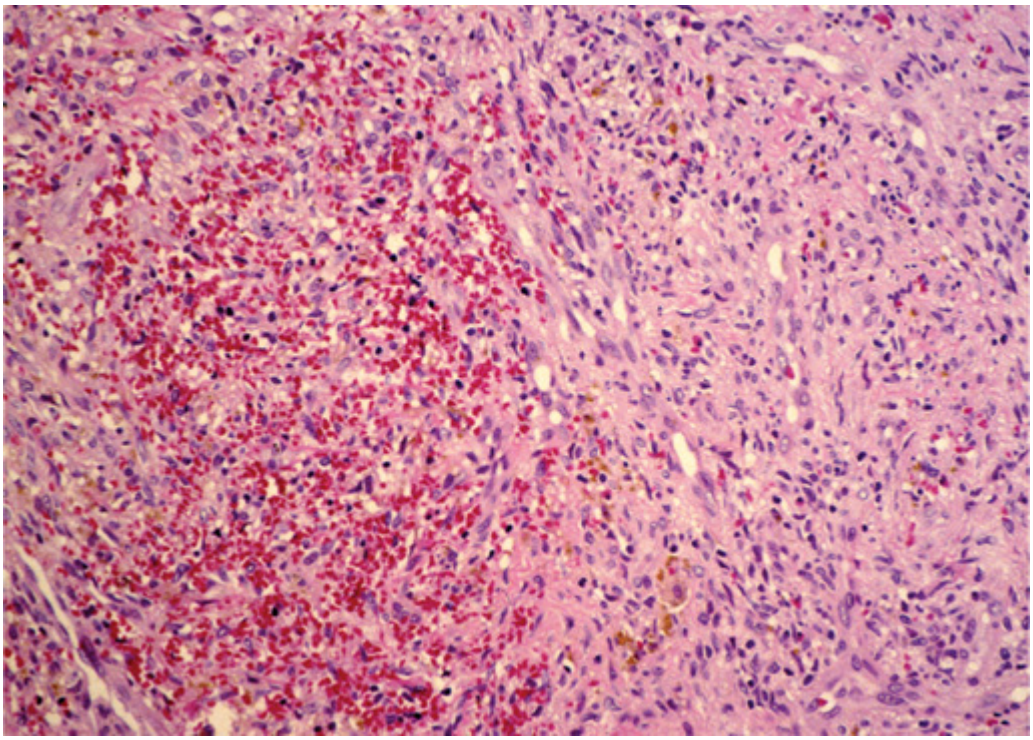

FIGURE 57-32 Hemangioendothelioma in lymph node with spindled and retiform growth patterns.A mixed pattern of solid collagenous areas *(right)* and anastomosing vasoformative areas *(left)* are common. The degree of atypia and number of mitoses are typically lower in epithelioid hemangioendothelioma than in angiosarcoma.

Bone Marrow Hematopoietic Elements and Tumors Involving Lymph Nodes

The presence of bone marrow hematopoietic elements in lymph nodes, also known as extramedullary hematopoiesis, occurs in a variety of settings, most commonly in association with myeloproliferative neoplasms with fibrosis, reflecting the altered

bone marrow environment. In such cases, megakaryocytes and other bone marrow elements appear in great numbers in the interfollicular areas of lymph nodes (**Fig. 57-36A–C**).

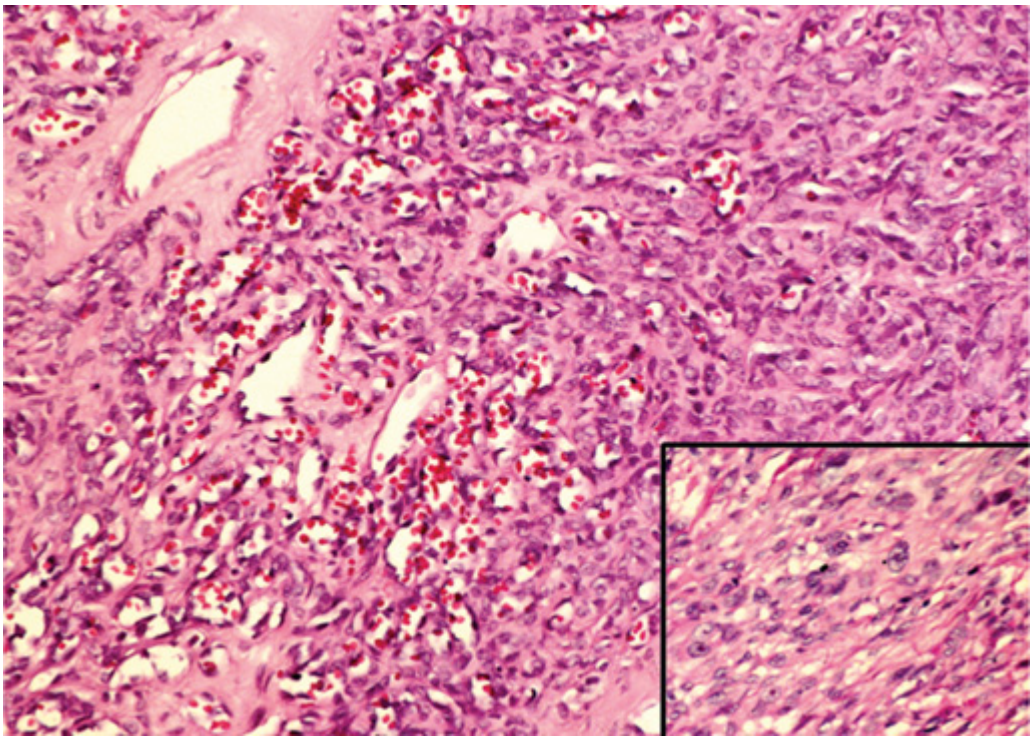

FIGURE 57-33 Angiosarcoma metastatic to lymph node.These tumors can have a wide variety of appearances, often with vasoformative areas mixed with cellular spindle cell areas *(inset)*.

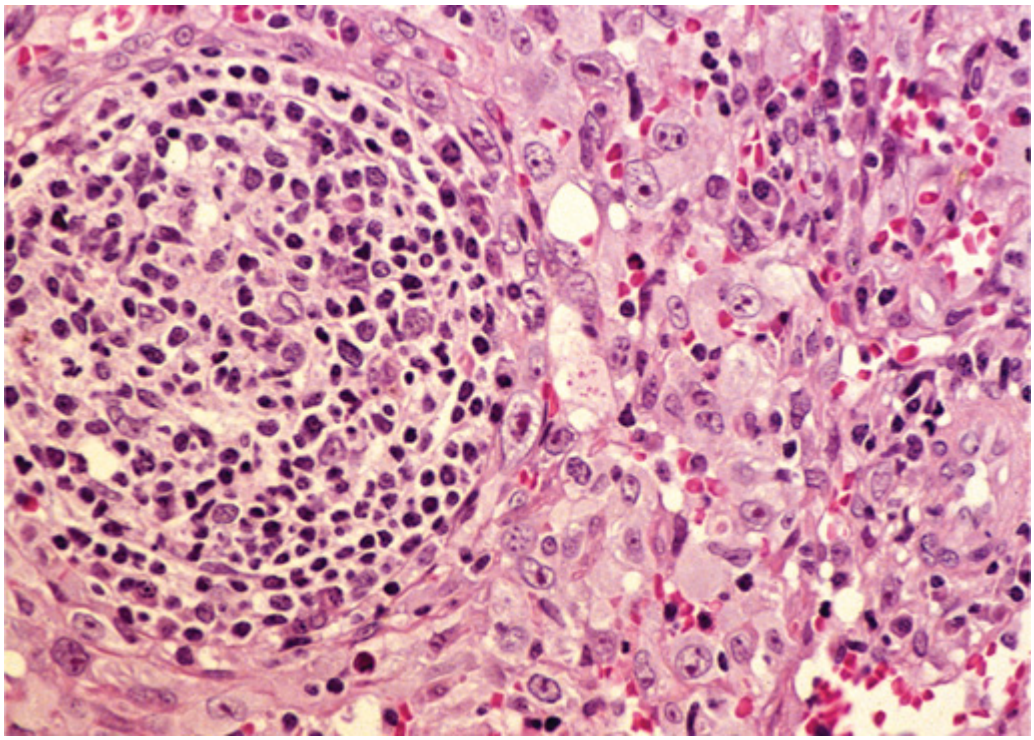

FIGURE 57-34 Epithelioid angiosarcoma metastatic to lymph node.An interfollicular pattern of tumor invasion is noted.

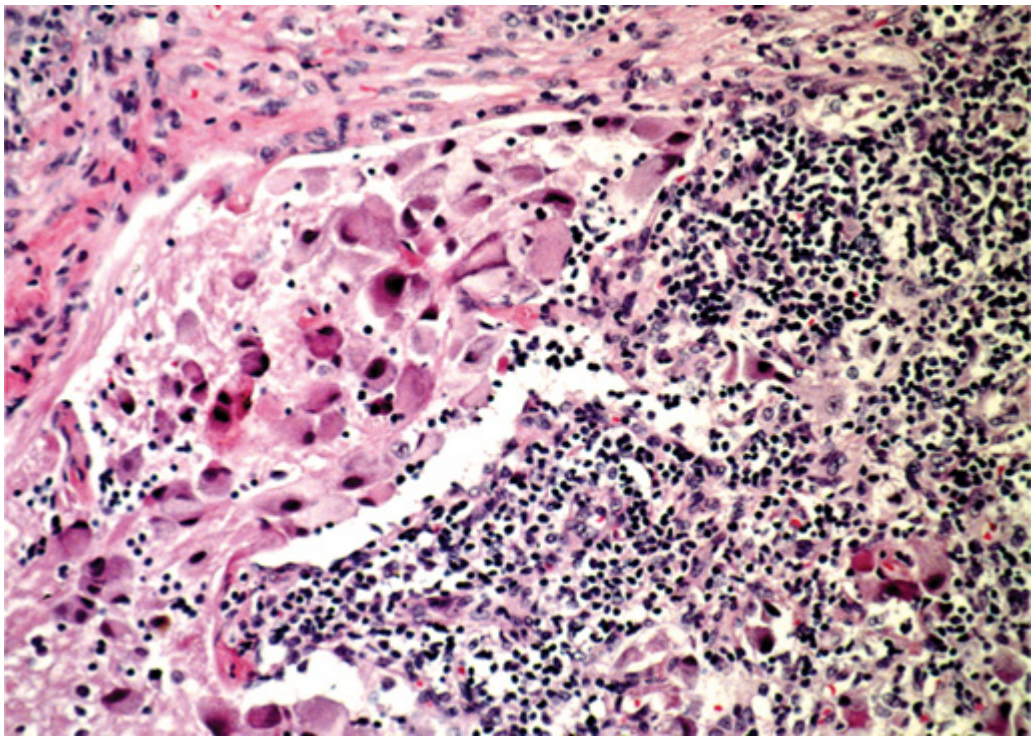

FIGURE 57-35 Metastatic ganglioneuroblastoma.Sinusoidal infiltration by spindled tumor cells with granular cytoplasm is noted. This patient had a history of a large posterior mediastinal mass.

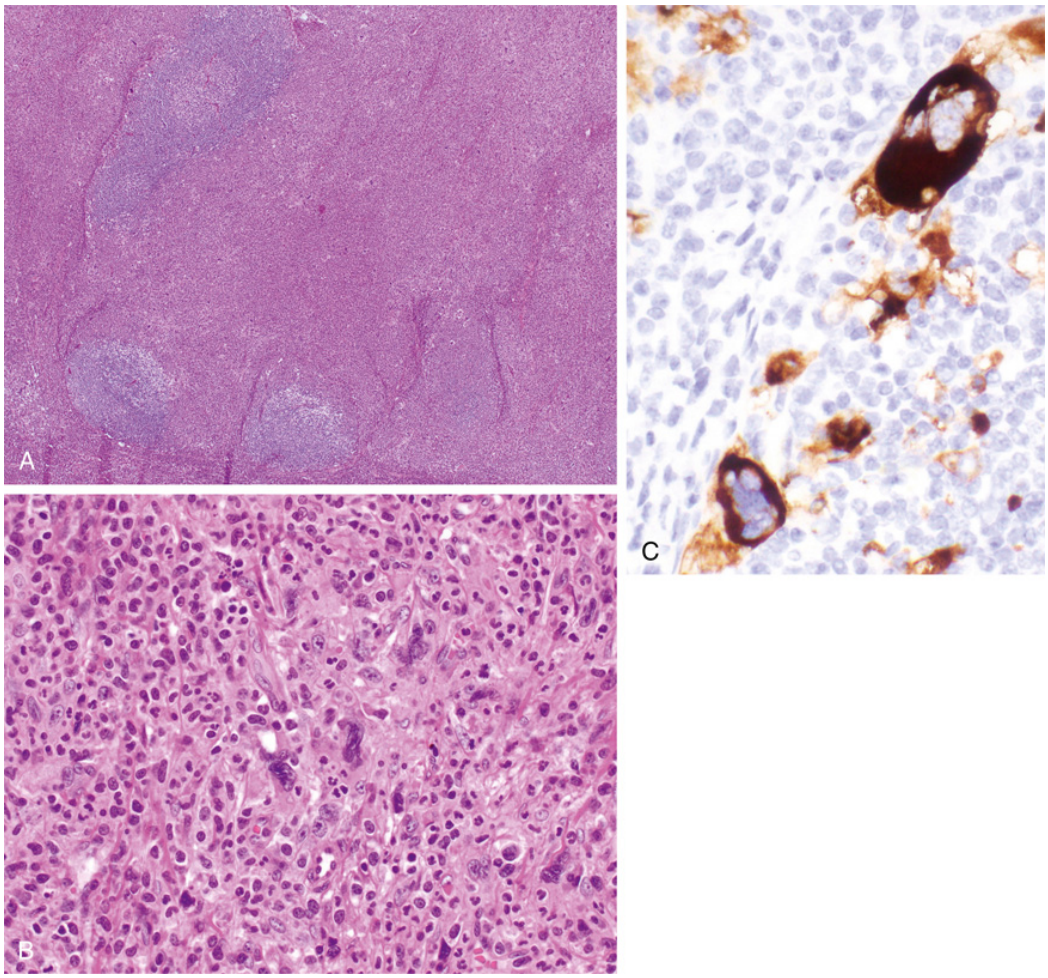

FIGURE 57-36 Extramedullary hematopoiesis in lymph node.**A,** Residual, primary, and secondary follicles are surrounded by a paracortical infiltrate containing numerous immature and maturing myeloid forms and scattered megakaryocytes **(B)** that stain positively for CD61 **(C)**.

Lymph nodes may be secondarily involved by acute leukemias and may be the first site of disease detection. Acute lymphoblastic leukemia involving lymph nodes resembles lymphoblastic lymphoma, as discussed in **Chapter 41**. An interfollicular pattern

can be observed in lymphomas with early spread. Acute myeloid leukemia involving lymph nodes (myeloid sarcoma) is discussed in **Chapter 46**. The interfollicular pattern of infiltration in acute myeloid leukemia (**Fig. 57-37**) and the cytologic features, especially as seen on touch preparations, are clues to the correct diagnosis. The inclusion of CD45/LCA in routine immunohistochemical panels should detect most of these tumors, but the antibody is negative in a subset of cases. Other stains, such as myeloperoxidase, lysozyme, CD43, CD33, CD68, and CD117, are helpful for diagnosis.

Nodal involvement by mast cell disease is discussed in **Chapter 49**. Mast cell tumors in the lymph node are often associated with perivascular fibrosis and eosinophils—two clues to the correct diagnosis. Low-grade tumors can have abundant pale cytoplasm, resembling nodal marginal zone B-cell lymphoma. High-grade tumors can be difficult to distinguish from other poorly differentiated neoplasms. Metachromatic staining with Giemsa or toluidine blue and IHC stains for tryptase and CD117 are helpful in establishing the diagnosis.

Langerhans cell histiocytosis is a relatively common finding in lymph nodes and is discussed in **Chapter 52**. Rarely, these tumors can resemble poorly differentiated non-hematopoietic tumors and should be considered when the first round of IHC is negative. The strong, uniform immunoreactivity of tumor cells for CD1a and S-100 protein distinguishes these tumors from other histiocytic proliferations, which are negative or only focally positive.

Conclusion

The evaluation of non-hematopoietic disorders in the bone marrow and lymph nodes requires careful correlation with clinical, imaging, and other laboratory findings and communication with the patients' physicians. IHC stains may be used as an adjunct to diagnosis and may also be used for prognostic or therapeutic purposes with certain tumors. When evaluated properly, examination of these organs is a powerful tool for both hematopoietic and non-hematopoietic diagnoses.

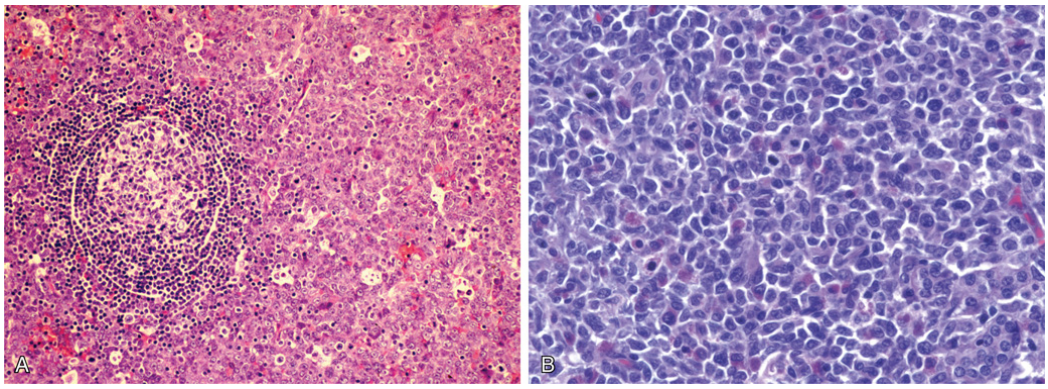

FIGURE 57-37 Acute myeloid leukemia in lymph node.**A,** The interfollicular areas are expanded by a neoplastic proliferation of immature myeloid forms. **B,** In this case of acute myeloid leukemia with inv(16) or *CBFB*::*MYH11* presenting as monoblastic sarcoma involving a lymph node, the blasts have folded or irregular nuclei consistent with monocytic differentiation, and numerous background eosinophils are present.

Pearls and Pitfalls

- Both the bone marrow biopsy and the aspirate are important in the evaluation of metastatic disease. Some tumors, such as neuroblastomas, may show only rare clusters on aspirates, even when there is extensive involvement.
- Request bone marrow biopsies, even in pediatric patients, when looking for metastatic disease. Bilateral bone marrow biopsies increase the likelihood of finding metastases.
- Biopsy of radiologically suspicious sites may be necessary to identify focal bone or bone marrow involvement.
- Lymph node location is often the most helpful clue to the primary site of origin of metastatic carcinoma. For instance, occult nasopharyngeal carcinoma commonly presents in neck lymph nodes.
- Sarcomatoid carcinoma should always be considered when a poorly differentiated spindle cell nodal metastasis is encountered.
- Anaplastic large-cell lymphoma can have a variety of appearances and exhibit the loss of nearly all lymphoid-associated markers. Perform CD30 IHC before ruling out a nodal large-cell malignancy.
- Follicular dendritic cell neoplasms often have an epithelioid or anaplastic morphology that mimics other tumors. A panel of follicular dendritic cell markers (CD21, CD23, CD35) is recommended because of partial differentiation. Residual

nodal tissue may show colonization of lymphoid follicles by dysplastic follicular dendritic cells.

- Do not make a diagnosis based on subset of positive immunohistochemical stains; a variety of tumors may show lineage infidelity (e.g., melanoma can express CD10, and carcinomas outside the lung may be positive for TTF-1).
- When possible, use IHC controls that have been fixed and processed (e.g., decalcified) in the same way as the specimen being tested.
- Metastatic tumors are best classified based on the primary site, even though the bone marrow or a peripheral lymph node may be more accessible.
- Always correlate findings with the clinical history and radiologic findings and talk to clinicians; a skeptical clinician is a pathologist's best friend.
- Hesitate before making an unlikely diagnosis but realize that anything is possible.

Chapter 58: Spleen: Normal Architecture and Neoplastic and Non-neoplastic Lesions

Attilio Orazi, and Daniel A. Arber

OUTLINE

The Normal Spleen

Gross Examination

Diffuse Splenic Enlargement

Focal Splenic Pathology

Splenic Rupture

Lymphoid Hyperplasia

Castleman Disease

Autoimmune Lymphoproliferative Syndrome

Hodgkin Lymphoma

Non-Hodgkin Lymphomas

Primary Splenic Lymphoma

Secondary Splenic Involvement by Lymphoma

Precursor Lymphoid Neoplasms

Systemic or Secondary Mature B-Cell Lymphomas and Leukemias

PRIMARY B-CELL LYMPHOID NEOPLASMS PRESENTING WITH PROMINENT SPLENOMEGALY

Mature T-Cell and Natural Killer–Cell Neoplasms

T-Cell Lymphoid Neoplasms Presenting With Prominent Splenomegaly

Myeloid Neoplasms

Myeloproliferative Neoplasms

Systemic Mastocytosis

Proliferations of the Monocyte-Macrophage System

Hemophagocytic Syndromes

MESENCHYMAL TUMORS AND NON-NEOPLASTIC DISORDERS THAT MIMIC NEOPLASMS

Splenic Hemangioma

Littoral Cell Angioma

Splenic Angiosarcoma

Splenic Lymphangioma

Sclerosing Angiomatoid Nodular Transformation of the Spleen

Peliosis

Splenic Hamartoma

EPSTEIN-BARR VIRUS—POSITIVE INFLAMMATORY FOLLICULAR DENDRITIC CELL/FIBROBLASTIC RETICULAR CELL TUMOR AND REACTIVE PSEUDOTUMORAL LESIONS OF THE SPLEEN

Epstein-Barr Virus–Positive Inflammatory Follicular Dendritic Cell/Fibroblastic Reticular Cell Tumor

Splenic Cysts

Other Tumors

STORAGE DISEASES

Few hematologic malignancies arise primarily in the spleen; most conditions occurring at this site represent secondary involvement by diseases originating elsewhere in the body. The role of the pathologist in most cases is to confirm the known or suspected diagnosis and to exclude unsuspected pathology. Careful gross evaluation of the organ and optimal tissue fixation are essential for the successful interpretation of splenic pathology. Because of the amount of blood in the spleen, thin sections are particularly important. In addition, care must be exercised in isolating lymph

nodes of the splenic hilum. Their examination can provide valuable additional information, particularly in the diagnosis of low-grade B-cell lymphomas. Obtaining adequate clinical information is often critical for the diagnostic characterization of disorders that involve the spleen; this need cannot be overemphasized.

In this chapter, we present a comprehensive account of those aspects of splenic pathology likely to be encountered by diagnostic hematopathologists. We outline principles for a systematic histopathologic analysis that can be applied to achieve a specific diagnosis after the recognition of broad categories of abnormalities affecting individual splenic compartments. To avoid repetition of material covered elsewhere in this text, specific splenic disease entities, such as hepatosplenic T-cell lymphoma and splenic marginal zone lymphoma, are only mentioned briefly. The reader is directed to the specific chapters covering these entities and to chapters covering other hematopoietic tumors that may secondarily involve the spleen, such as Hodgkin lymphoma and the various non-Hodgkin lymphomas.

Table 58-1

The Normal Spleen

The characterization of disorders that involve the spleen can best be understood in light of the structure and function of that organ.[1-7] The spleen is composed of two anatomically and functionally distinct regions (**Table 58-1**). The lymphoid tissue of the spleen, called the *white pulp*, appears grossly as uniformly distributed white nodules. The white pulp is intimately associated with the splenic arterial

circulation. The central arteries, which arise from trabecular arteries within the fibrous trabeculae, are surrounded by cylindrical cuffs of lymphocytes called *periarteriolar lymphoid sheaths*. The periarteriolar lymphoid sheaths contain an admixture of B cells and T cells, with a predominance of CD4-positive T lymphocytes. Periodically, splenic lymphoid follicles (Malpighian corpuscles) occur as outgrowths of the periarteriolar lymphoid sheaths. The morphology of the splenic white pulp varies with age and with its functional activity (e.g., presence of antigenic stimulation). Inactive or hypoplastic white pulp, in which no germinal centers are seen, is characteristic of infancy, senescence, and the immunologically unstimulated adult spleen. In the immunologically activated state, the splenic lymphoid follicle shows three distinct zones. The *germinal center,* structurally similar to germinal centers in other lymphoid organs, is surrounded by a *mantle zone*. The mantle zone is encased by the outer *marginal zone,* a cellular layer at the interface between the white and red pulp. The marginal zone, composed of both B cells and T cells,[4] is the site of initial antigen trapping and processing (**Fig. 58-1**).

The red pulp contains the terminal branches of the splenic artery, which end in specialized capillaries known as *sheathed capillaries*. These unique capillaries simply terminate and outlet their contents into the surrounding red pulp, a functional arrangement known as *open splenic circulation*.[8] The *red pulp* of the spleen is mainly composed of splenic vascular sinuses and the splenic cords, also known as *cords of Billroth*, which are made up of splenic macrophages, scattered cord capillaries, venules, and stromal cells. All these cellular elements linked together, along with a relatively

scanty amount of extracellular matrix, are responsible for the peculiar architecture of the red pulp. The splenic vascular sinuses provide the mechanism for filtration of the peripheral blood, one of the important functions of the spleen. The sinus-lining cells, also known as *littoral cells*, have long cytoplasmic processes that overlap and are closely apposed. However, because no tight junctions are present, circulating blood cells are able to squeeze through the interendothelial junctions and percolate through the splenic cords before entering the splenic sinuses, venules, and trabecular veins, eventually draining into the splenic vein, thus returning to the systemic circulation. The ability of circulating blood cells to enter the splenic sinuses and subsequently percolate through the cords depends on their deformability. Cells without the ability to deform cannot enter the sinuses and are destroyed in the acidotic, hypoxic environment of the cords of Billroth.[2,9,10]

The T cells found in the red pulp are predominantly CD8-positive small lymphocytes, which are rarely found in the periarteriolar lymphoid sheaths and are virtually absent in the germinal centers. Gamma-delta T cells also reside normally in the red pulp.[11] The distribution of immunoglobulin-containing B cells is comparable to that seen in the lymph nodes. The mantle zone B cells bear surface immunoglobulin, with co-expression of immunoglobulin (Ig) M and IgD. The marginal zone B cells predominantly express IgM, with only a small minority expressing IgD. IgG expression is lacking in these areas and is limited to scattered cells in the red pulp, where rare IgA-containing cells are also found. The red pulp contains numerous cells of monocyte-macrophage lineage, only a few of which are found in the white pulp. Natural killer (NK) cells are found scattered

throughout the red pulp. The red pulp also contains granulocytes, monocytes, and lymphocytes that pass transiently through the red pulp circulation.

Gross Examination

The initial evaluation of the spleen should consist of a gross examination of the organ. Three major patterns are recognized, based on involvement of the white pulp, red pulp, or more focal lesions (**Table 58-2**).

Diffuse Splenic Enlargement

White Pulp Involvement

Most proliferative disorders of the splenic lymphoid tissue produce a micronodular pattern owing to the abnormal expansion of preexisting splenic lymphoid structures (follicles and periarteriolar lymphoid sheaths). Grossly, multiple small, whitish nodules are noticeable on the cut surface, an appearance that is occasionally referred to as a *miliary pattern*. This pattern is most often seen in small B-cell lymphoid neoplasms, other than hairy cell leukemia, involving the spleen. The nodules occasionally become confluent or present as larger, dominant masses. Lymphoid malignancies that affect the white pulp are largely the same as those that affect lymph nodes. These disorders include classic Hodgkin lymphoma, nodular lymphocyte predominant B-cell lymphoma (World Health Organization [WHO]: nodular lymphocyte predominant Hodgkin lymphoma) and non-Hodgkin lymphomas, primarily of B-cell lineage.

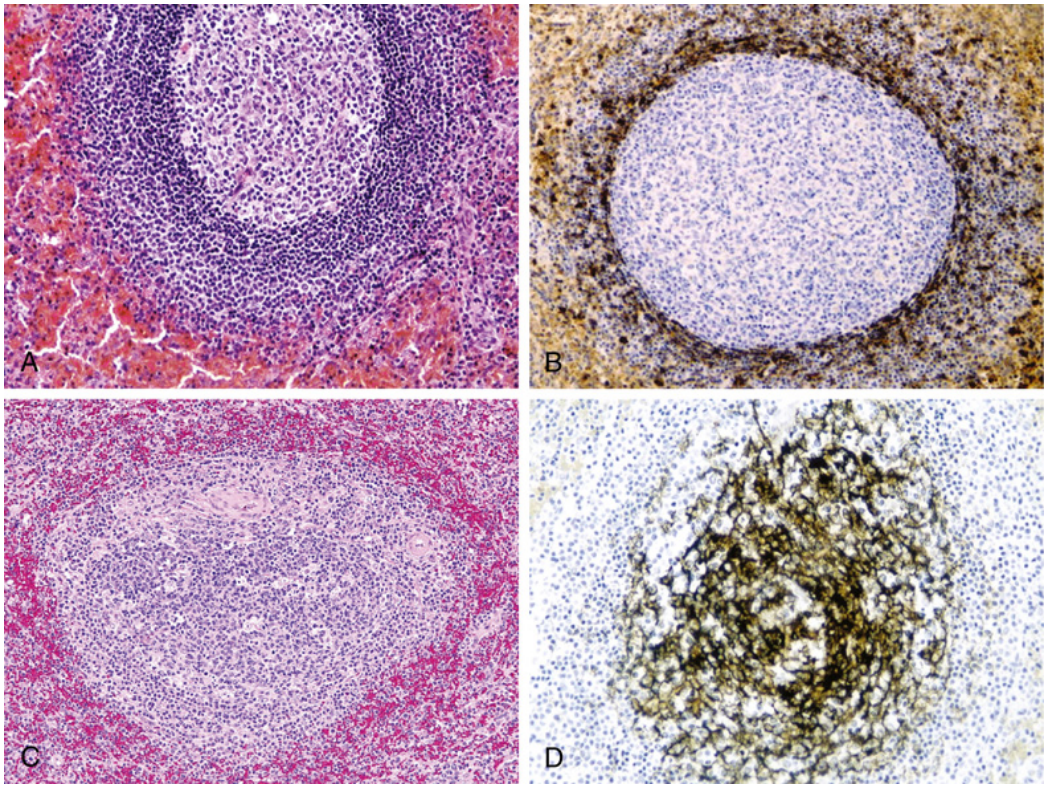

FIGURE 58-1 **A,** Splenic lymphoid follicle displaying its characteristic tripartite nature: germinal center, mantle zone, and well-defined marginal zone. **B,** DBA.44 immunohistochemical stain highlights mantle zone cells. Note negative staining in the follicle germinal center and rare positive cells within the predominantly negative marginal zone. **C,** Hyperplastic follicle, with less distinct mantle and marginal zones. **D,** CD21 immunohistochemical stain highlights the follicular dendritic cell network within a germinal center.

Table 58-2

CLL/SLL, Chronic lymphocytic leukemia/small lymphocytic lymphoma; *DLBCL,* diffuse large B-cell lymphoma; *EBV-DCT,* Epstein-Barr virus–positive inflammatory follicular dendritic cell/fibroblastic reticular cell tumor; *HCL,* hairy cell leukemia; *HPS,* hemophagocytic syndrome; *LPL,* lymphoplasmacytic lymphoma; *MCL,* mantle cell lymphoma; *MPN,* myeloproliferative neoplasm; *PTCL,* peripheral T-cell lymphoma; *SMZL,* splenic marginal zone lymphoma; *T-LGLL,* T-cell large granular lymphocytic leukemia; *T-PLL,* T-cell prolymphocytic leukemia.

* Focal lesions may have considerable overlap, with both red pulp and white pulp involvement. At times, this division is arbitrary.

† Diffuse involvement is seen in systemic angiomatosis, as well as in some cases of littoral cell angioma.

Red Pulp Involvement

Red pulp involvement has a different gross appearance. Typically, expansion of the red pulp gives the spleen a more homogeneous red or “beefy” appearance. The normal nodularity of the white pulp is typically diminished or not seen. Microscopically, the white pulp is often atrophic or compressed by the expanded red pulp. Neoplastic proliferations that involve the red pulp include myeloid and lymphoid leukemias, myeloproliferative neoplasms, and a variety of nonhematopoietic tumors. In general, disorders with a large component of circulating cells (e.g., chronic lymphocytic leukemia, T-cell large granular lymphocytic leukemia, hairy cell leukemia, and acute leukemia) have significant red pulp involvement. However,

some lymphomas (e.g., hepatosplenic T-cell lymphoma, intravascular large B-cell lymphoma, as well as other less well-defined lymphoid malignancies) also involve the red pulp.

Focal Splenic Pathology

Some benign and malignant proliferations produce focal lesions rather than more diffuse involvement of the red or white pulp. These include lesions that involve vascular, stromal, and hematolymphoid elements.

Splenic Rupture

Pathologic rupture of the spleen can be seen in a variety of hematologic disorders, both benign and malignant.[5] Spontaneous rupture of the spleen should always prompt a pathologic evaluation of the splenic tissue because various infectious causes (particularly infectious mononucleosis) have pathologic findings that are distinctive enough to make a presumptive diagnosis or suggest additional serologic studies. Other causes, such as storage diseases, present with characteristic findings as well. Splenic rupture as a primary presentation of hematologic malignancy is rare, but it has been reported with both low-grade and high-grade lymphoid malignancies. Acute and chronic myeloproliferative disorders and, rarely, acute lymphoblastic leukemia can present as splenic rupture. Nonhematopoietic lesions associated with splenic rupture include cysts, infarctions, vascular lesions or neoplasms, and metastatic malignancies.

Lymphoid Hyperplasia

Various reactive conditions that affect the splenic white or red pulp can simulate hematopoietic malignancies (**Box 58-1**). Reactive follicular hyperplasia, with the formation of germinal centers, is usually easily recognized as benign (see **Fig. 58-1**).[2] However, follicular hyperplasia must occasionally be distinguished from follicular lymphoma. The finding of tingible body macrophages and a polymorphic lymphoid cell population within polarized splenic follicles points to the diagnosis of a reactive hyperplasia. A rare condition that may grossly simulate lymphoma is localized (nodular) reactive lymphoid hyperplasia. The area of nodular hyperplasia appears quite distinct from adjacent normal spleen and may raise the suspicion of lymphoma (**Fig. 58-2**). Histologically, this area is composed of a focal aggregation of hyperplastic follicles that have typical, benign features.[12]

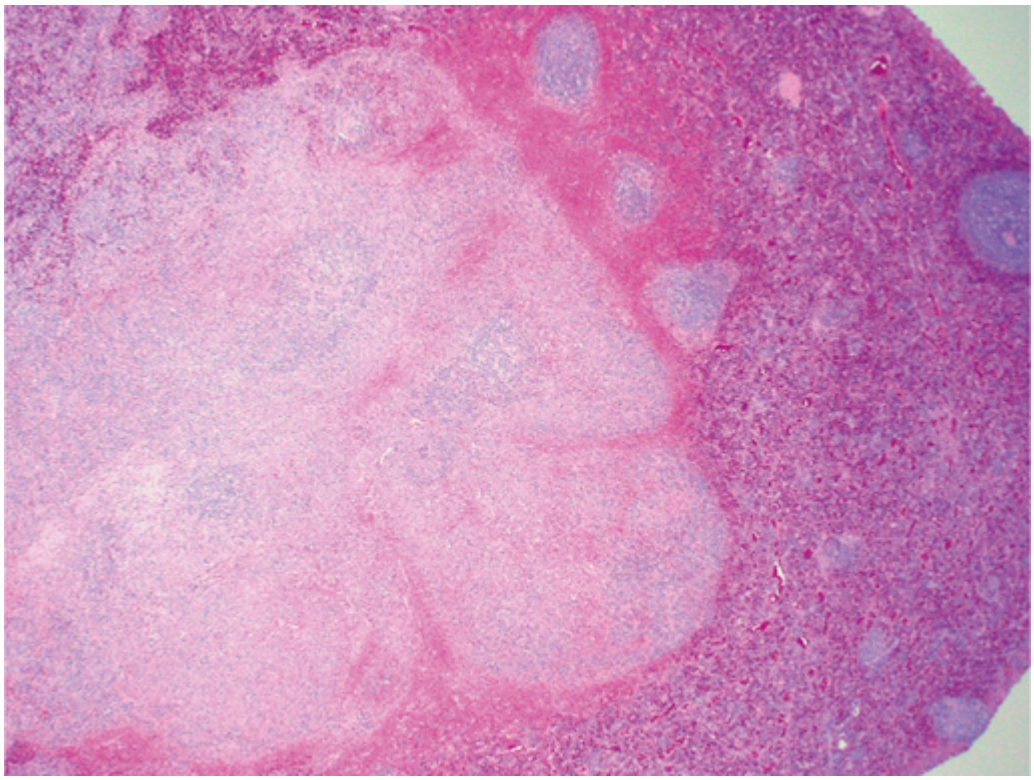

FIGURE 58-2 Nodular lymphoid hyperplasia of the spleen.Note the confluence of several hyperplastic follicles, which form a tumor-like lesion. This is surrounded by normal red pulp and other hyperplastic-appearing follicles. Although cytologically benign, this entity can mimic lymphoma or other focal splenic lesions.

Box 58-1 Benign Lesions of the Spleen That Simulate Hematopoietic Malignancies

- Immune reactions
  - Florid follicular hyperplasia
  - Marginal zone hyperplasia

- Congenital immunodeficiencies
- Autoimmune conditions
- Disorders of the reticuloendothelial system
    - Storage diseases
    - Hemophagocytic syndrome
- Castleman disease
- Reactive myeloid proliferations caused by cytokine treatment
- Nonhematopoietic lesions
    - Cyst
    - Hamartoma
    - Inflammatory pseudotumor

In some cases, marginal zones may become widely expanded, a phenomenon referred to as *splenic marginal zone hyperplasia*.[2,5,13-15] This usually occurs in association with follicular hyperplasia, but such expansions may also occur with B-cell lymphomas other than splenic marginal zone lymphoma, particularly follicular lymphoma. It may be impossible to distinguish these reactive changes from cases of early marginal zone lymphoma on morphologic grounds alone,[16] although reactive marginal zone hyperplasia is usually not associated with an increase in red pulp B cells, which is common in true splenic marginal zone lymphoma.[14] Some autoimmune disorders can result in splenic marginal zone hyperplasia, including systemic lupus erythematosus or idiopathic thrombocytopenic purpura.

Reactive lymphoid hyperplasia without germinal center formation, which is characteristic of infectious mononucleosis, as well as herpes simplex and other viral infections, can simulate both Hodgkin and non-Hodgkin lymphoma.[2,17] The white pulp in these conditions

lacks expanded follicles and, on low-power examination, resembles the immunologically unstimulated spleen.[2,5,7,18,19] This is the splenic equivalent of paracortical hyperplasia as seen in lymph nodes, being similarly characterized by an interfollicular T cell hyperplasia. Occasionally, reactive paracortical hyperplasia may take the appearance of small to large nodules composed of T cells. High-power examination reveals morphologic evidence of antigenic stimulation, characterized by the presence of lymphocytes in varying stages of transformation, including small and large lymphocytes, often with plasmacytoid features, and immunoblasts. Transformed lymphocytes and immunoblasts also proliferate around splenic arterioles and may infiltrate the subendothelial zones of the trabecular veins and the connective tissue framework, resulting in splenic rupture in extreme cases.[2] This pattern of lymphoid hyperplasia can also be seen in immunocompromised individuals, such as patients treated with steroids or other immunosuppressive therapies for conditions such as immune thrombocytopenic purpura or autoimmune hemolytic anemia.[20] Some peripheral T-cell lymphomas may produce a similar pattern of white pulp expansion. Nodular T-cell hyperplasia, simulating a peripheral T-cell lymphoma, can rarely be observed in patients with hypersensitivity reactions to phenytoin.[21] Abnormalities of the white pulp that may be worrisome for lymphoma can also be seen in patients with congenital conditions characterized by immunodeficiency or by abnormalities causing deregulated lymphoid production (e.g., autoimmune lymphoproliferative syndrome).

Castleman Disease

Occasional cases of Castleman disease of both the unicentric hyaline-vascular type and the multicentric type associated with human herpesvirus 8 (HHV-8)/Kaposi sarcoma-associated herpesvirus (KSHV) reportedly occur in the spleen.[22-25] Multicentric Castleman disease represents the majority of cases reported in more recent years. Splenic involvement is rare in the unicentric form, and most such reports are from the older literature, before cases were evaluated for HHV-8/KSHV; thus, the nature of these proliferations is not clearly established. The white pulp is expanded, with hypervascular germinal centers; the red pulp shows marked plasmacytosis. As seen in lymph nodes, immunoblastic cells expressing IgMλ are distributed in the perifollicular areas of the white pulp.[24] Multicentric Castleman disease is generally negative for Epstein-Barr virus (EBV), but rare cases resembling germinotropic lymphoproliferative disorders have been described. These tumors are coinfected with EBV and HHV-8/KSHV.[25]

Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome is a rare disorder that can mimic lymphoma in the spleen. It is a hereditary disorder, usually caused by mutations of the *FAS (CD95)* gene,[26,27] that presents in early childhood (younger than 2 years). Autoimmune lymphoproliferative syndrome is characterized by lymphoid hyperplasia, autoimmunity, and splenomegaly; the spleen frequently enlarges to more than 10 times its age-normal size. Histologically, the white pulp shows variable degrees of follicular hyperplasia, often with enlarged marginal zones. The periarteriolar lymphoid sheaths

and red pulp are also expanded, owing to a markedly increased number of T cells (**Fig. 58-3**). These cells consist of a mixture of small lymphocytes and immunoblasts. As in lymph nodes in this disorder, many of these T cells are negative for both CD4 and CD8. The pathologic picture of the spleen is complicated by the frequent association with immune cytopenias affecting red blood cells, granulocytes, and platelets, contributing to splenomegaly.[28,29] Patients with this disorder have an increased risk of having both Hodgkin and non-Hodgkin lymphomas.[30]

Hodgkin Lymphoma

Although the spleen is the most common extranodal organ involved by Hodgkin lymphoma,[31,32] primary Hodgkin lymphoma of the spleen is extremely rare.[2,33] The documentation of splenic involvement has therapeutic and prognostic implications, although these implications now appear to be less critical in light of the high rates of remission and cure obtained with current regimens of combination chemotherapy. Involvement of the liver and bone marrow is rarely found in the absence of splenic involvement.[31] All histologic subtypes of Hodgkin lymphoma can involve the spleen; nodular sclerosis and mixed cellularity are the most common,[31] and involvement by nodular lymphocyte predominant B-cell lymphoma (previously termed *nodular lymphocyte predominant Hodgkin lymphoma*) is less common.[34] On the contrary, widespread involvement, including of the subdiaphragmatic region, and splenic involvement have been associated with lymphocyte-depleted classic Hodgkin lymphoma.[35]

Hodgkin lymphoma produces either small miliary nodules or, more frequently, solitary or multiple tumor masses in the spleen (**Fig. 58-4**).[2,5] Splenic involvement is generally detectable grossly but may be subtle (**Fig. 58-5**). Foci of involvement may be only a few millimeters in size.[36,37] For this reason, the gross examination of the spleen must be meticulous in patients with Hodgkin lymphoma so that small foci of involvement are not missed. The early lesions of Hodgkin lymphoma in the spleen are found microscopically in the periarteriolar lymphoid sheaths or in the marginal zones.[5] As the disease progresses, the nodules expand to efface the lymphoid follicles and may involve the red pulp.

Sarcoid granulomas may be found in the spleens of patients with Hodgkin lymphoma, in addition to various other disorders associated with abnormal T-cell function.[38,39] The granulomas are not related to prior lymphangiography, and their origin is unknown. Several studies have suggested that granulomas occur more frequently in spleens uninvolved by Hodgkin lymphoma than in those involved by the disease.[40,41] Grossly, the granulomas may be so large as to mimic involvement by Hodgkin lymphoma. Microscopically, the granulomas are composed of clusters of epithelioid histiocytes that occur in the white pulp in close association with the arterial circulation. It has been suggested that patients with splenic sarcoid granulomas may have a better prognosis.[41]

The criteria for the diagnosis of Hodgkin lymphoma in the spleen are the same as those for other nonnodal sites (see **Chapters 26** and **27**). The subclassification of Hodgkin lymphoma in the spleen is sometimes difficult and is unnecessary in cases with a previous nodal

diagnosis. However, the unique morphologic and immunophenotypic characteristics of nodular lymphocyte predominant B-cell lymphoma allow its distinction from the classic Hodgkin lymphoma subtypes (see **Chapter 26**).

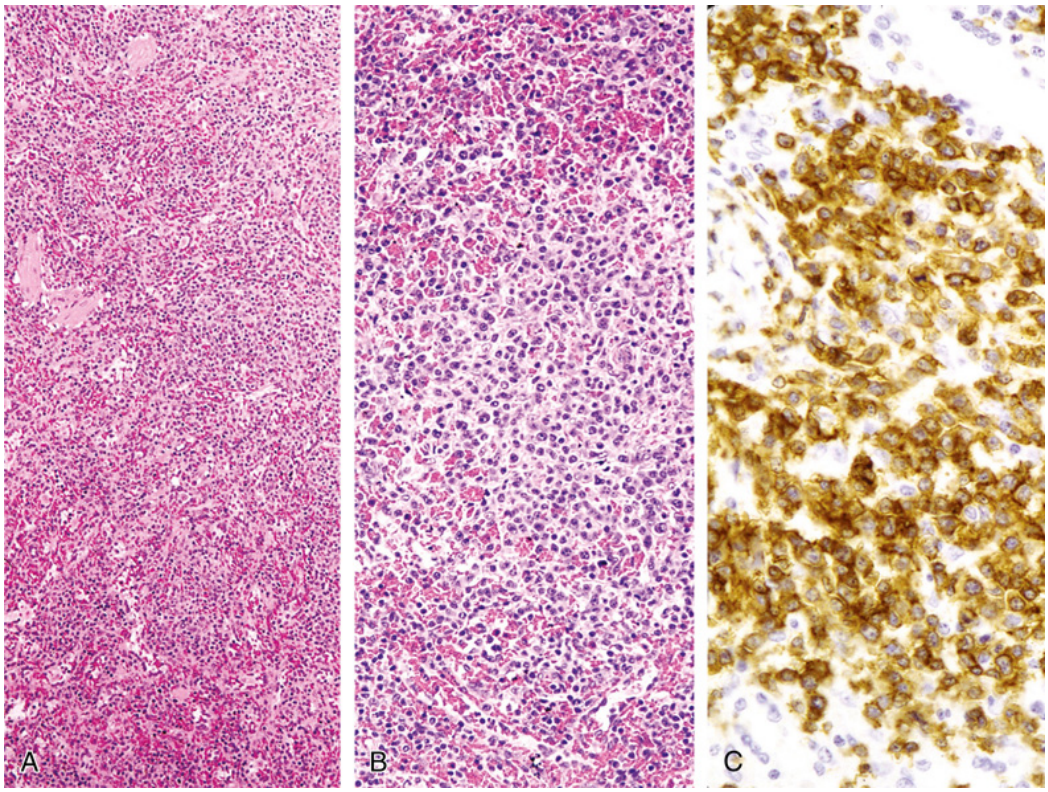

FIGURE 58-3 Splenic involvement in autoimmune lymphoproliferative syndrome.**A,** Low power shows atypical lymphoid hyperplasia that could easily be confused with lymphoma. Note the absence of reactive germinal centers, caused by prolonged steroid treatment. **B,** Higher magnification shows hyperplastic periarteriolar lymphoid sheaths and surrounding red pulp containing an increased number of atypical-appearing lymphocytes. **C,** CD3 stain demonstrates the T-cell nature of the proliferating lymphocytes.

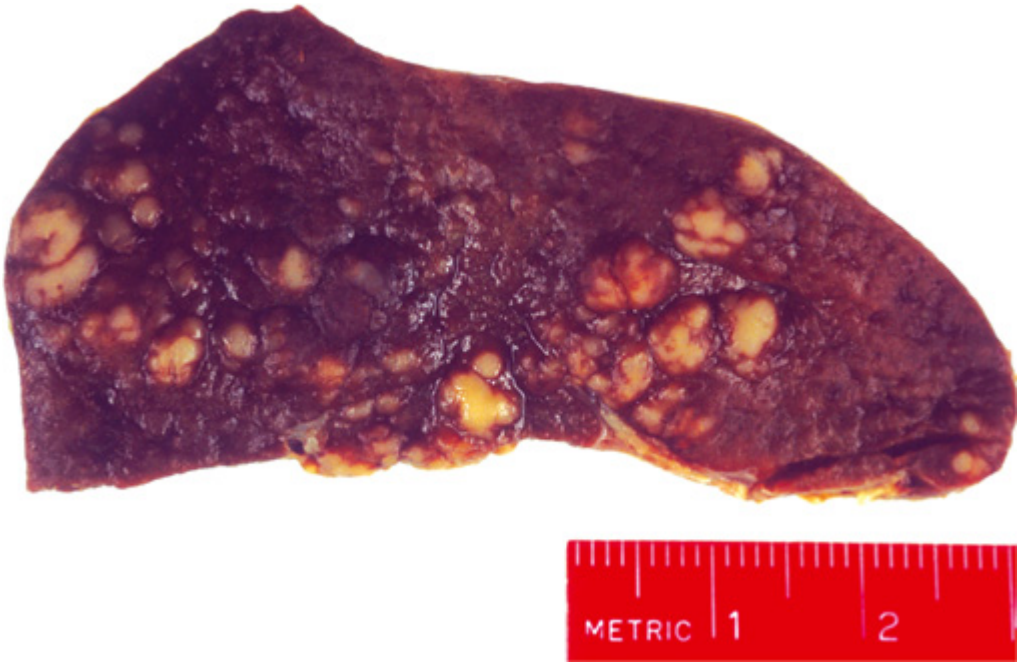

FIGURE 58-4 Gross photograph of Hodgkin lymphoma involving the spleen.Hodgkin lymphoma can present with a single mass or multiple discrete nodules. Thin sections after fixation are particularly valuable in detecting subtle involvement.

Non-Hodgkin Lymphomas

Non-Hodgkin lymphomas may involve the spleen in three clinical settings. In the first and rarest setting, termed *true primary splenic lymphoma*, the tumor is confined to the spleen or splenic hilar lymph nodes, without evidence of involvement of other sites. In the second and most common setting, the organ is involved as part of generalized, systemic lymphomatous spread. In the third setting, the lymphomatous process is characterized by prominent or

predominant splenomegaly and often distinctive clinicopathologic features.

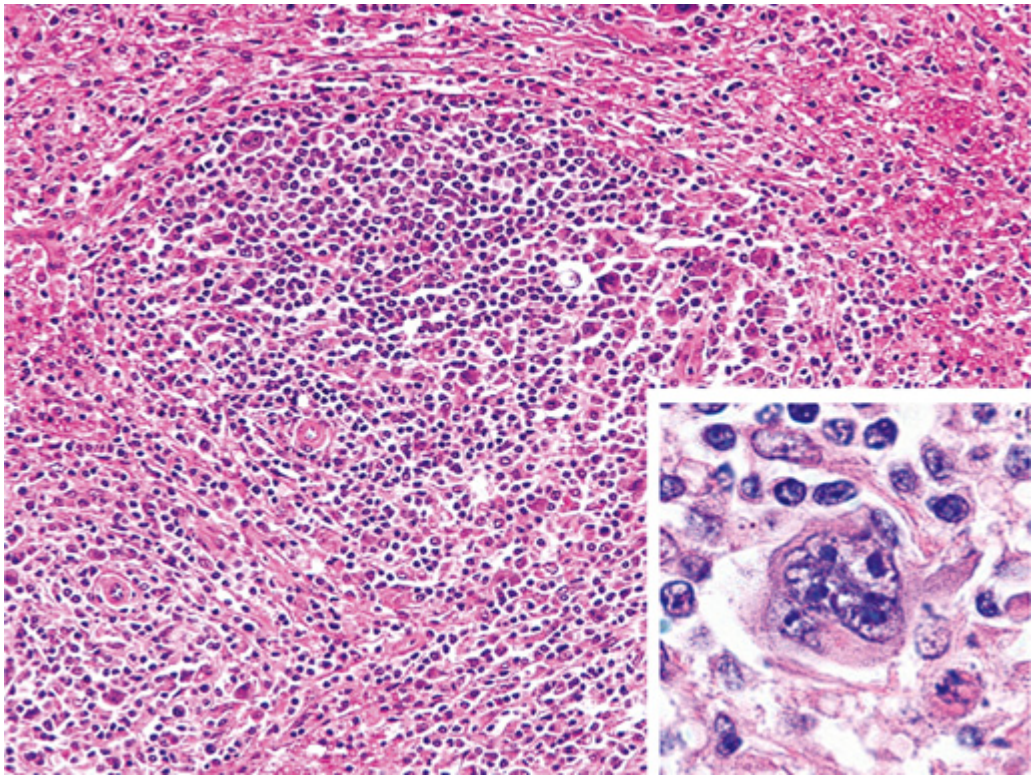

FIGURE 58-5 Early involvement of the spleen by Hodgkin lymphoma.Reed-Sternberg cells are seen within a polymorphic cellular background in perifollicular areas. *Inset,* Higher magnification shows classic Reed-Sternberg cells.

Primary Splenic Lymphoma

Primary splenic lymphoma is rare, accounting for less than 1% of all lymphomas. Those primary to the spleen are described in separate chapters of this text and have been recently reviewed elsewhere.[42] Excluding lymphomas thought to arise in the spleen, such as splenic

marginal zone lymphoma, most of these cases were described in the older literature and are not well defined.[43-53] Two cases occurred in HIV-positive patients,[44,45] and rare cases have been associated with hepatitis C infection.[52] Several studies of primary splenic lymphomas fulfilling the most stringent diagnostic criteria (i.e., tumor confined to the spleen and splenic hilar lymph nodes) include almost entirely adult patients with a slight male preponderance.[43,53] The most common presenting symptoms include left-sided abdominal pain and systemic symptoms such as fever, malaise, and weight loss. The gross findings and the histologic characteristics were similar to those observed in spleens secondarily involved by malignant lymphoma. Most reported cases are of B-cell lineage. Large B-cell lymphoma, some showing CD5 expression,[50,51] appears to be the most common subtype, with the remainder being mostly low-grade B-cell malignancies. A report of 32 patients presenting with follicular lymphoma first diagnosed in the spleen identified two variants: one with the t(14;18), high BCL2, and CD10 expression, similar to nodal follicular lymphoma, and a second subset that lacked t(14;18) and was of a higher histologic grade.[54] The majority of patients relapsed with systemic disease.

Secondary Splenic Involvement by Lymphoma

Clinical assessment of the likelihood of splenic involvement by malignant lymphomas may be difficult. The weights of involved spleens vary widely.[55] Although tumor involvement usually results in palpable splenomegaly, Goffinet and colleagues[56] found that approximately one-third of nonpalpable spleens were involved by lymphoma at staging laparotomy. Staging laparotomy has been

replaced by imaging studies; positron emission tomography, in particular, provides an accurate determination.[57]

Non-Hodgkin lymphomas of different types involve the spleen with variable frequency. Splenic involvement is particularly frequent in low-grade B-cell lymphomas. As mentioned earlier, evaluation of splenic hilar lymph nodes is very important. Histologic findings of lymphoma that are ambiguous or incompletely diagnostic in splenic sections may be more distinctive in splenic hilar lymph nodes. Liver involvement by lymphoma is rare in the absence of splenic disease.

Precursor Lymphoid Neoplasms

Although enlargement of the spleen often occurs during the course of either B-lymphoblastic or T-lymphoblastic malignancies, it rarely approaches clinical significance. The histopathologic features are similar to those of other leukemic disorders, with diffuse infiltration of the red pulp by blast cells.[5]

Systemic or Secondary Mature B-Cell Lymphomas and Leukemias

Most B-cell lymphomas involve the spleen in one of two main patterns: with uniform nodular expansion of the white pulp, as seen in small B-cell lymphomas such as chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), splenic marginal zone lymphoma, mantle cell lymphoma, and follicular lymphoma (**Fig. 58-6**); or with the formation of single or multiple tumor masses, as seen in most cases of diffuse large B-cell lymphoma (DLBCL) (**Fig. 58-7**).[5,19] Occasionally, the spleen is the site of large-cell transformation of a low-grade B-cell lymphoma (**Fig. 58-8**).

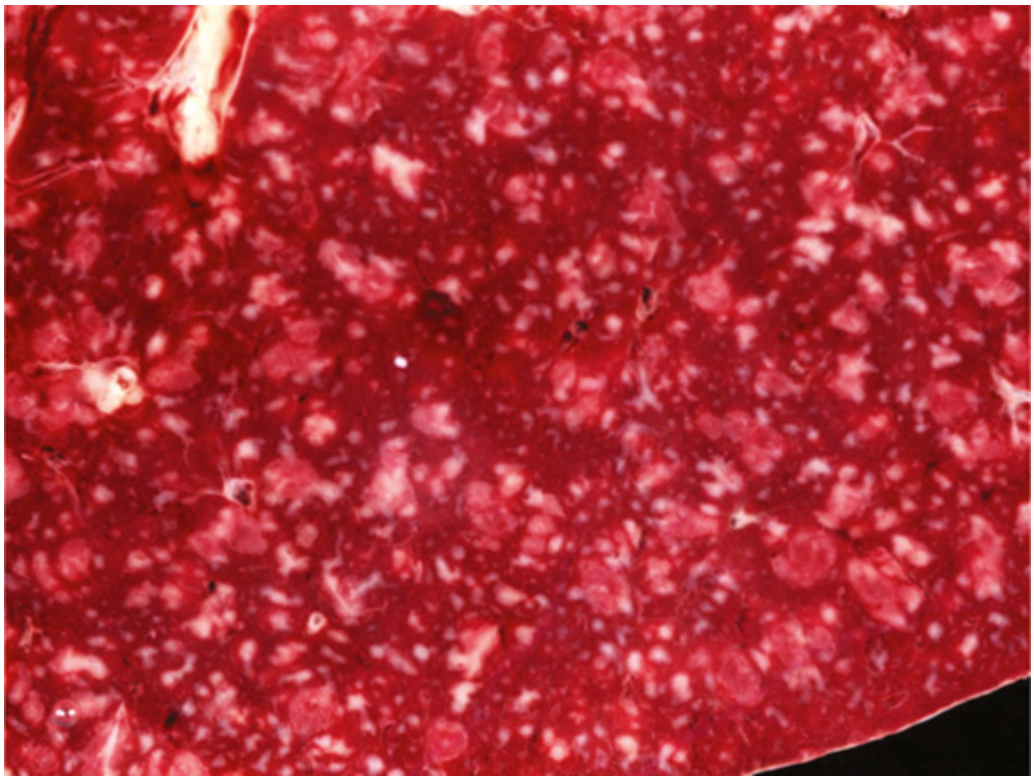

FIGURE 58-6 Gross photograph of miliary involvement of the spleen by low-grade B-cell lymphoma.This is an exaggeration of the normal white pulp appearance and is seen in lymphomas that preferentially involve the white pulp.

FIGURE 58-7 Gross photograph of diffuse large B-cell lymphoma involving the spleen. Large single or multiple tumor masses are not typically seen in low-grade lymphomas; they are more common in more aggressive lymphomas.

Splenomegaly is often a common presenting feature for secondary involvement of the spleen by mature B-cell lymphoma and leukemia and is particularly common in patients with B-cell prolymphocytic leukemia and lymphoplasmacytic lymphoma. Although the gross and histologic patterns of splenic involvement of the various mature B-cell lymphomas and leukemia may vary, the morphologic and immunophenotypic features are similar to those described in other sites. The reader is referred to the various chapters specific to the mature B-cell lymphomas and leukemias elsewhere in this text, including the nonnodal type of mantle cell lymphoma[58] that is associated with prominent splenomegaly without adenopathy (see

Chapter 21). Three fairly distinctive patterns of splenic infiltration have been described in DLBCL. DLBCL in the spleen characteristically produces solitary or multiple tumor masses that are usually well demarcated and may show areas of necrosis. Predominant diffuse, red pulp involvement, however, may be observed in a small subset of cases,[47,59-62] with features similar to intravascular large B-cell lymphoma of other sites. Finally, a micronodular pattern of infiltration by T-cell/histiocyte-rich large B-cell lymphoma may occur and often mimics a reactive process. The spleen in these micronodular cases is markedly enlarged, but without distinct nodules. Small aggregates of lymphocytes and histiocytes are distributed in the red pulp and white pulp. The histiocytes are especially abundant, and neoplastic large B cells may be difficult to identify without the use of immunohistochemical studies.[60]

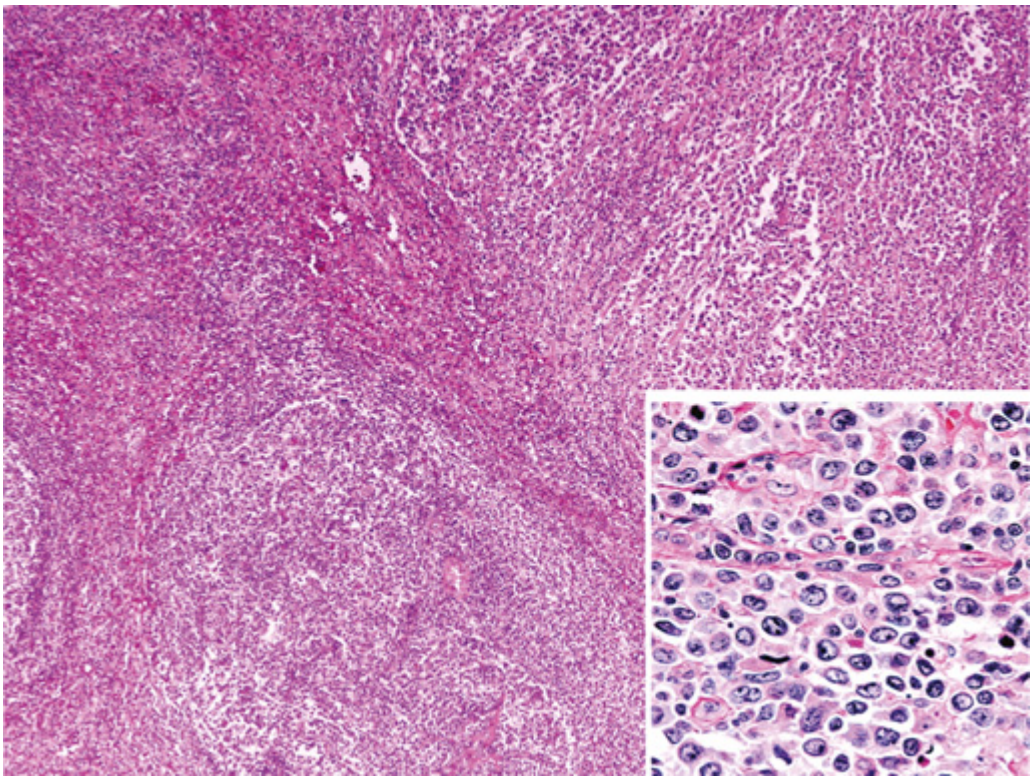

FIGURE 58-8 Low-power photomicrograph of follicular lymphoma *(lower left)* transforming to diffuse large B-cell lymphoma *(upper right)*. *Inset,* Higher magnification of the large-cell lymphoid component shows cytologic features consistent with a centroblastic subtype.

Primary B-Cell Lymphoid Neoplasms Presenting With Prominent Splenomegaly

Several types of B-cell lymphoma/leukemia are primary to the spleen. These include splenic marginal zone lymphoma, splenic diffuse red pulp small B-cell lymphoma, hairy cell leukemia variant, and hairy cell leukemia. Because these disorders represent distinct

clinical or provisional entities, such descriptions are not duplicated here; they are covered in specific chapters in this text that provide detailed descriptions of the splenic findings (see **Chapters 15** and **16**).

Mature T-Cell and Natural Killer–Cell Neoplasms

Mature T-cell and NK-cell malignancies are relatively uncommon, and few studies have focused on the splenic pathology. Among the nonleukemic forms, splenic involvement is relatively common in cases of advanced-stage mycosis fungoides/Sézary syndrome. Splenic involvement in mycosis fungoides usually affects the white pulp and red pulp alike.[63] The marginal zones and the periarteriolar lymphoid sheaths are infiltrated by large, atypical cells, associated with both diffuse and patchy nodular involvement of the red pulp.[63,64] Not all cells have cerebriform nuclear contours, and a variable proportion of the tumor cells may appear blastic.

The node-based peripheral T-cell lymphomas (PTCLs) are perhaps the least-studied group of T-cell neoplasms that occur in the spleen. The pattern of splenic involvement in these diseases is different from that in B-cell lymphomas and is centered more on the red pulp.[18,65-67] We have seen a variety of patterns of involvement—some expanding the periarteriolar lymphoid sheath, some producing discrete masses, and one mimicking the pattern seen in mycosis fungoides. The lymphoepithelioid cell (Lennert) variant,[68] a cytologic subtype of PTCL, not otherwise specified, is characterized by a high content of epithelioid histiocytes. Early involvement usually occurs in the peripheral zones of follicles and the

periarteriolar lymphoid sheaths, consistent with the T-cell origin of this lymphoma. The epithelioid histiocytes tend to localize in a ringlike arrangement at the periphery of the white pulp, but they occasionally form clusters.[68] Although originally thought to be characteristic of this type of lymphoma, the ringlike arrangement of epithelioid cells may be seen in other forms of both B-cell and T-cell lymphoma. The epithelioid cells may be difficult to differentiate from the sarcoid type of granulomas sometimes seen in the spleens of patients with Hodgkin lymphoma. Some cases of PTCL with marked splenomegaly have been associated with hemophagocytic syndrome.[69,70] In these cases, expansion of the red pulp predominates, and the erythrophagocytic histiocytes may overshadow the neoplastic T cells. A hemophagocytic syndrome may be seen with both T-cell and NK-cell malignancies, many of which are associated with EBV.

T-Cell Lymphoid Neoplasms Presenting With Prominent Splenomegaly

Several types of T-cell lymphomas and leukemias present with splenomegaly and distinct clinicopathologic characteristics, but these are discussed elsewhere in this text. Hepatosplenic T-cell lymphoma (see **Chapter 33**) and T-cell prolymphocytic leukemia (see **Chapter 31**) both present with pronounced splenomegaly and diffuse red pulp infiltration. T-cell large granular lymphocytic leukemia (see **Chapter 30**) also involves splenic red pulp but in contrast with the former two, spares the white pulp and often has less splenic enlargement.

Myeloid Neoplasms

Red pulp disease is characteristic of splenic involvement in leukemic processes (**Fig. 58-9**).[5,71] The leukemic cells usually appear localized to the cords of Billroth, with secondary involvement of the sinuses. Peritrabecular and subendothelial deposits may be seen early in the course of leukemic infiltration. Although splenic involvement is invariable in leukemic disorders, the degree of splenomegaly depends on the type of leukemia and the duration of the disease. The acute leukemias usually result in only mild-to-moderate splenic enlargement, but the chronic leukemias may produce prominent splenomegaly that often results in hypersplenism. Peripheral cytopenias may necessitate splenectomy, which may be effective in ameliorating the cytopenias but usually does not affect the course of the underlying disease. Splenic rupture is an occasional complication of leukemia. This is thought to result from tumor cells infiltrating the trabecular framework and vascular structure of the organ or from infarction within the spleen. Rupture of the spleen is far more common in the chronic leukemias (particularly chronic myeloid leukemia) than in the acute forms.[72]

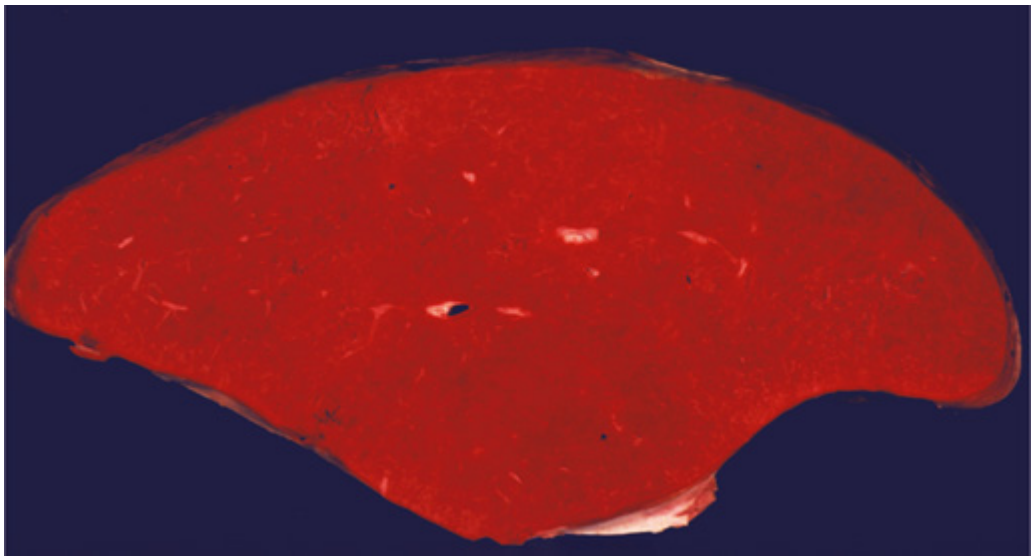

FIGURE 58-9 Leukemic involvement of the spleen.Disorders characterized by red pulp involvement, such as acute and chronic leukemias, produce a uniform red to purple appearance. The normal white pulp nodularity is typically absent.

Splenectomy is rarely performed in patients with the various types of acute myeloid leukemia (AML) (see **Chapter 46**), and a primary diagnosis of AML is very unusual in that setting. Splenectomy caused by massive splenomegaly is relatively common, however, in patients with some myeloproliferative neoplasms (MPNs). For this reason, a more detailed description of the splenic changes in these disorders is provided.

Myeloproliferative Neoplasms

The MPNs are a group of chronic, interrelated clonal disorders of the hematopoietic stem cell.[73,74] These disorders include polycythemia vera, primary myelofibrosis, essential thrombocythemia, and chronic

myeloid leukemia. A variable degree of splenomegaly occurs in all these disorders. Although each has its own somewhat distinctive "splenic" characteristics,[75] a precise diagnostic subtyping of the MPNs cannot be based on a morphologic examination of the spleen alone; this requires relevant clinical and laboratory data, as well as an examination of bone marrow and peripheral blood smears. The reader is directed to **Chapter 47** for a more detailed description of the diagnostic criteria for each disorder.

Chronic Myeloid Leukemia

Chronic myeloid leukemia (CML) is frequently associated with massive splenomegaly. The cut surface of the spleen is deep red, without visible white pulp, because CML generally obliterates the lymphoid follicles, although small remnants of white pulp are occasionally seen.[5] Infarcts are common because of subendothelial invasion of the splenic trabecular veins, and fibrosis of the cords may be prominent. Histologic examination reveals a polymorphic cellular infiltrate in the red pulp, which includes myeloid cells at all stages of maturation.[5] The identification of immature myeloid cells (i.e., promyelocytes, myelocytes) can be facilitated with immunohistochemical stains for CD34, CD117, CD68 (or CD68R), and myeloperoxidase (or lysozyme) in combination with the enzymatic chloroacetate esterase reaction (Leder stain); the latter is particularly strongly expressed in promyelocytes. Localized collections of ceroid-containing histiocytes (pseudo–Gaucher cells), similar to those seen in the bone marrow, may also be observed in the spleens of CML patients.

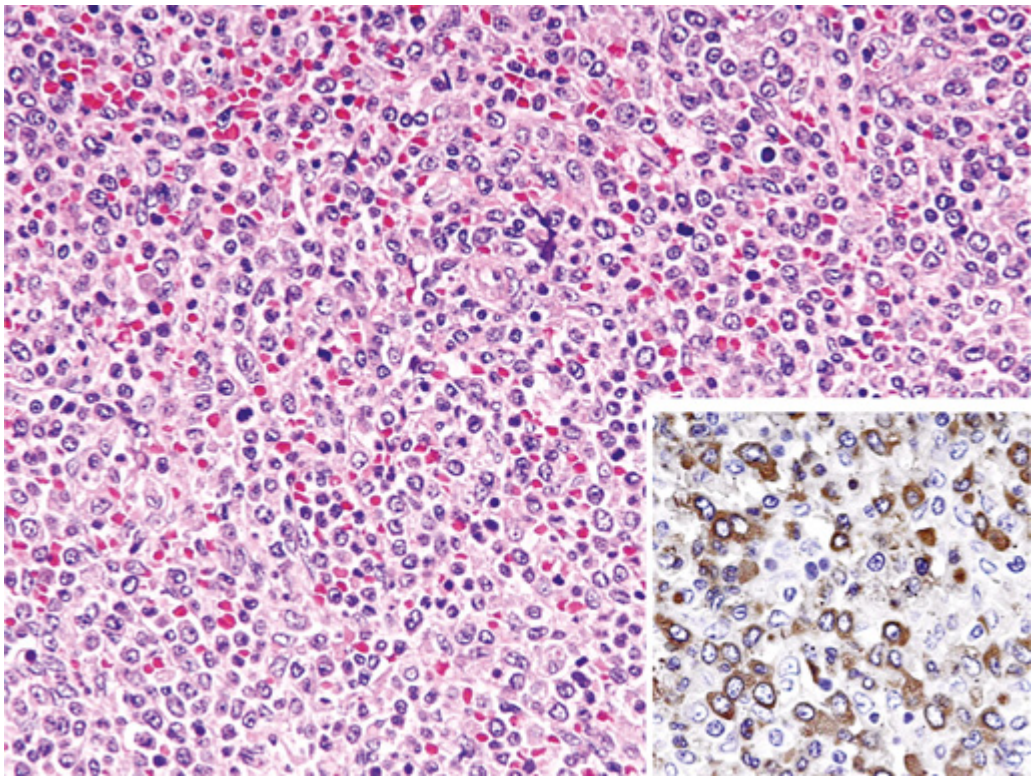

FIGURE 58-10 Left-shifted granulocytic hyperplasia in the spleen induced by granulocyte colony-stimulating factor.The red pulp is diffusely occupied by promyelocytes and other immature granulocytic forms, a finding that could be interpreted as evidence of acute myeloid leukemia. *Inset,* Myeloperoxidase immunostain highlights the myeloid cells.

CML may terminate with the development of an accelerated or blastic phase that resembles de novo acute leukemia. Approximately one-third of cases of blast crisis arise in an extramedullary site, most commonly the spleen. Blast crisis in CML may result in a dramatic increase in spleen size.[76] Several studies have indicated that the myeloid cells in the spleen develop additional cytogenetic

abnormalities before this occurs in such cells at other sites,[77-82] and they may proliferate in the spleen more rapidly than at other sites of blastic transformation.[82] Gross examination may reveal a homogeneous cut surface or, in some cases, discrete nodules that represent discrete collections of blasts.[5] Most often the blasts are myeloblasts, although they are lymphoblasts in approximately 25% of cases and megakaryoblasts or erythroblasts in rare cases. Immunohistochemistry with a panel of antibodies that includes both myeloid- and lymphoid-associated antigens (e.g., CD34, CD117, CD68, myeloperoxidase, CD42b [or CD61], TdT, CD79a [or PAX5], CD10, and CD3) may be helpful in confirming the presence of an increased number of blasts and in identifying their lineage.

Therapy with colony-stimulating factors (e.g., granulocyte colony-stimulating factor) may simulate splenic involvement with CML or another myeloid neoplasm (**Fig. 58-10**) or, occasionally, may even mimic extramedullary acute myeloid leukemia.[83] Rarely, the administration of this cytokine has been associated with splenic rupture.[83]

Polycythemia Vera

Splenomegaly occurs in the majority of patients with polycythemia vera. The degree of splenomegaly in the erythrocytotic phase of polycythemia vera is usually mild or moderate; the size of the spleen roughly correlates with the duration of the disease.[84-87] In approximately 15% of cases, however, polycythemia vera evolves to a spent phase, also called *postpolycythemic myeloid metaplasia*, in which the development of severe fibrosis in the bone marrow is

accompanied by leukoerythroblastosis in the peripheral blood and marked splenomegaly.[75,88,89]

Although it was previously thought that splenic enlargement in polycythemia vera results from myeloid metaplasia, it has been demonstrated that extramedullary hematopoiesis is not a feature of this disease before the development of reticulin fibrosis in the bone marrow.[88] Spleens in the erythrocytotic phase show intense congestion of the cords of Billroth and the sinuses of the red pulp, accompanied by a proliferation of cordal macrophages without significant myeloid metaplasia. In contrast, spleens obtained from patients whose disease has evolved to postpolycythemic myeloid metaplasia show prominent myeloid metaplasia indistinguishable from that observed in cases of de novo primary myelofibrosis.[88,89]

Primary Myelofibrosis

The degree of splenomegaly seen in cases of primary myelofibrosis (PMF), formerly termed *agnogenic myeloid metaplasia* or *idiopathic myelofibrosis with myeloid metaplasia*, is most striking among the MPNs. In fibrotic phase PMF, splenomegaly is associated with fibrosis in the bone marrow (graded at least as MF2) and the presence of leukoerythroblastosis (circulating erythroblasts in association with immature myeloid cells—usually myelocytes or metamyelocytes) and teardrop erythrocytes in the peripheral blood.[89,90] Symptoms related to massive enlargement of the organ may be the presenting feature of this disorder. The degree of splenomegaly correlates with disease duration.[85,86,89] Increasing splenomegaly may be arrested, but only transiently, by splenic

irradiation or chemotherapy. Spleen size can be decreased by *JAK2* inhibitory therapy.[91]

Splenomegaly in overt PMF results from the presence of clonal extramedullary hematopoiesis in the red pulp, also known as myeloid metaplasia. On gross examination, the spleen is enlarged and purple-red, with indistinct white pulp markings. Infarcts are common. In some cases, however, focal proliferations with grossly recognizable nodules, usually composed predominantly of one cell type, are observed.[5] Microscopic examination usually reveals multiple foci of extramedullary hematopoiesis distributed throughout the red pulp sinuses and in the splenic cords (**Fig. 58-11**; **Table 58-3**). Extramedullary hematopoiesis may be accompanied by a variable degree of fibrosis.

Histologically, although the hematopoiesis is always trilinear, one cell line may predominate in a given case.[75,82] Erythroid precursors occur in easily recognizable clusters, frequently in the sinuses. Megakaryocytes show the same atypical features as those seen in the bone marrow, with clusters of large, often bizarre forms. Although granulocytic precursors may be difficult to distinguish from cordal macrophages, they can be recognized in touch imprints or in tissue sections by using the immunoperoxidase technique with antibodies to myeloperoxidase or lysozyme.[75] Extramedullary hematopoiesis is accompanied by a proliferation of cordal macrophages, and phagocytosis of hematopoietic precursors may be seen.[5] The trilinear nature of the hematopoiesis seen in PMF aids in distinguishing this disorder from other types of myeloid neoplasms (e.g., CML). Blastic transformation in PMF may be heralded by an increase in immature cells. In these cases, the identification of an increased proportion of

blasts can be facilitated by the use of appropriate immunohistochemical stains, as previously described. In addition to CML, the differential diagnosis of myeloid metaplasia in the spleen includes various disorders associated with bone marrow fibrosis and peripheral blood leukoerythroblastosis. Metastatic carcinoma and infectious disorders that involve the bone marrow are well-known causes of bone marrow fibrosis that may mimic PMF to a certain extent. Others that are much less frequent include myelodysplastic syndrome (MDS),[92] myelodysplastic/myeloproliferative neoplasms (MDS/MPN) such as chronic myelomonocytic leukemia,[93] and juvenile myelomonocytic leukemia (**Fig. 58-12**).[94]

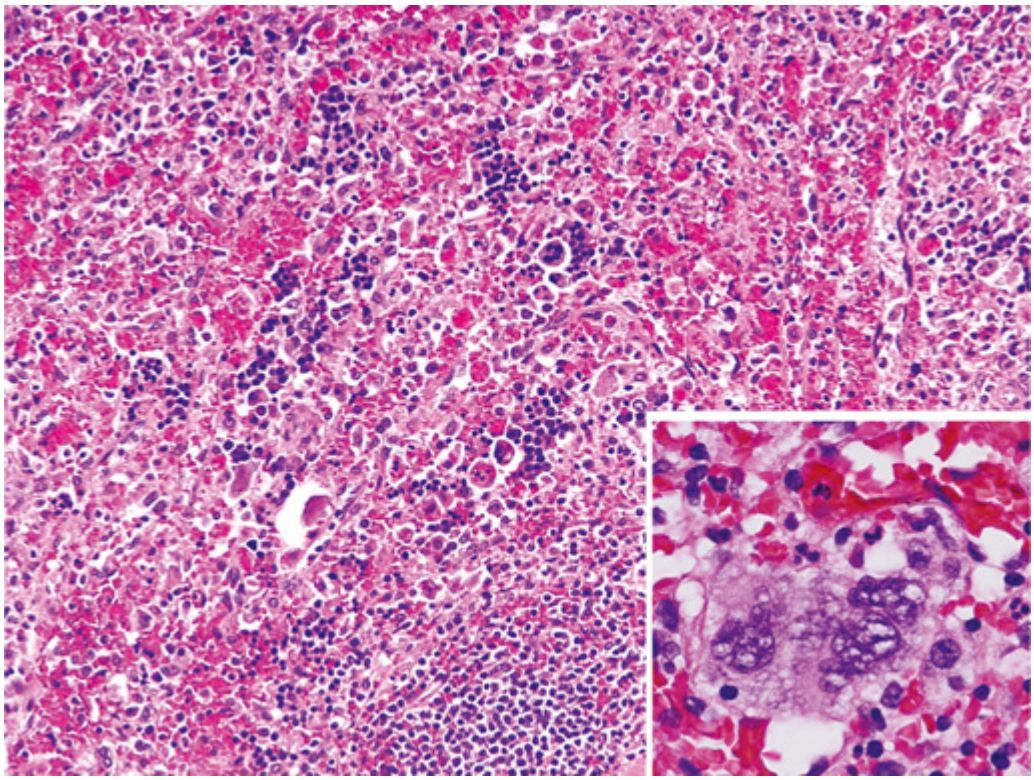

FIGURE 58-11 Extramedullary hematopoiesis in the spleen in a case of primary myelofibrosis.High-power photograph shows atypical megakaryocytes with cloudlike nuclear morphology and abnormally clumped chromatin *(inset)*. When reactive versus hematopoietic neoplasm–associated extramedullary hematopoiesis is compared, the presence of atypical megakaryocytes favors a clonal hematopoietic process.

Table 58-3

G-CSF, Granulocyte colony-stimulating factor; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm.

Essential Thrombocythemia

Essential thrombocythemia is characterized by a marked megakaryocytic proliferation in the bone marrow associated with thrombocytosis.[74,90] Clinical manifestations include hemorrhagic or, less commonly, thrombotic phenomena.[95] The degree of splenomegaly in essential thrombocythemia is usually less marked than that seen in the other chronic myeloproliferative disorders, and hypersplenism is not a common clinical manifestation. Because of the scarcity of splenectomy specimens, there are no large studies of the splenic pathology in essential thrombocythemia. In the few cases studied, the most notable finding was widening of the cords of Billroth, which may appear hypocellular at low power because of the presence of large masses of platelets, which may also be seen in the sinuses. Touch preparations of the spleen may be useful for demonstrating the sequestration of platelets. Although mild to moderate, splenomegaly is characteristic of most cases of essential thrombocythemia. In advanced cases, the spleen may become atrophic and nonfunctional, with atrophy probably resulting from infarction caused by the pooling of platelets.[96] The presence of fibrosis and microinfarcts (Gamna-Gandy bodies) may mimic the morphology of the spleen in advanced sickle cell disease. In our experience, no significant extramedullary hematopoiesis is seen. Occasionally, however, in the rare cases of essential thrombocythemia evolving to myelofibrosis, significant myeloid metaplasia reportedly occurs in the spleen.

Other Chronic Myeloid Neoplasms

Other types of myeloid neoplasms may produce splenomegaly. This complication is more likely to be associated with MDS/MPNs such as chronic myelomonocytic leukemia or juvenile myelomonocytic leukemia.[93,94] In these cases, the splenic red pulp contains an increased number of myelomonocytic cells (see **Fig. 58-12**). An increased number of blasts can be seen in cases undergoing acute transformation. Immunohistochemistry may be helpful to confirm the diagnosis and is necessary to confirm acute transformation. Aggregates of mature plasmacytoid dendritic cells (plasmacytoid monocytes) can also be observed in cases of chronic myelomonocytic leukemia[97,98] and in other types of myeloid neoplasms.

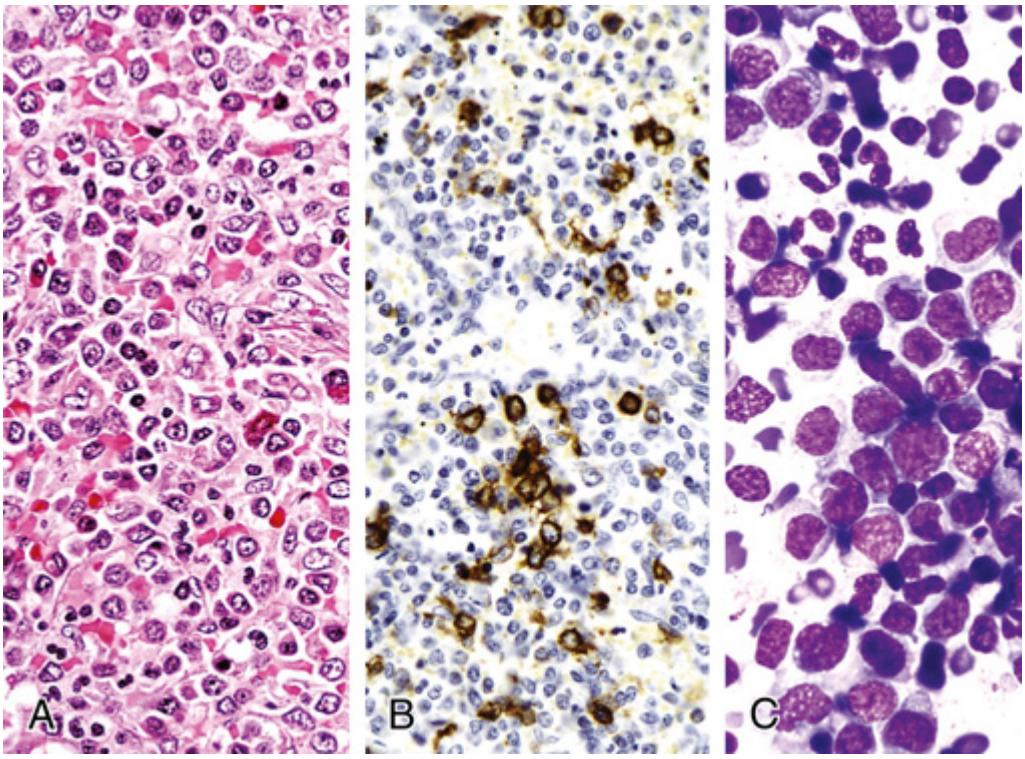

FIGURE 58-12 Juvenile myelomonocytic leukemia involving the spleen.**A,** The red pulp contains a polymorphic cellular population that includes blasts, other immature myeloid cells, monocytes, neutrophils, and eosinophils. **B,** CD34 stain highlights the presence of a variable proportion of blasts. **C,** Touch preparation of the spleen shows immature and mature granulocytic and monocytic cells (Wright-Giemsa stain).

Systemic Mastocytosis

The spleen is usually involved in systemic mastocytosis (reviewed more completely in **Chapter 49**), although the degree of splenomegaly is frequently only mild to moderate.[99-102] The pattern

of involvement of the spleen in mast cell disease is variable.[99-102] Early involvement may preferentially localize to paratrabecular areas or to the marginal zones of the white pulp. A characteristic fibroblastic reaction resulting in a concentric rimming of the lymphoid follicles may be observed (**Fig. 58-13**). Some investigators have reported a diffuse infiltration of the red pulp, and multinodular perivascular infiltrates have also been described.[102] Increased eosinophils are associated with the mast cell aggregates. Mast cells typically appear cuboid or spindle shaped, with pale nuclei and grayish cytoplasm. Mast cell granules can be demonstrated with chloroacetate esterase stain and are metachromatic with toluidine blue and Giemsa stains, although neoplastic mast cells are often hypogranular. Tryptase and CD117 positivity are helpful in confirming splenic involvement, particularly in cases associated with a marked fibroblastic reaction and relatively rare mast cells. Systemic mast cell disease may be associated with other clonal hematologic disorders, most notably chronic myelomonocytic leukemia, MPN, MDS, or acute myeloid leukemia,[103,104] which may be present concurrently in the spleen. Their identification within the splenic red pulp can be facilitated by immunohistology for myeloid-associated antigens.

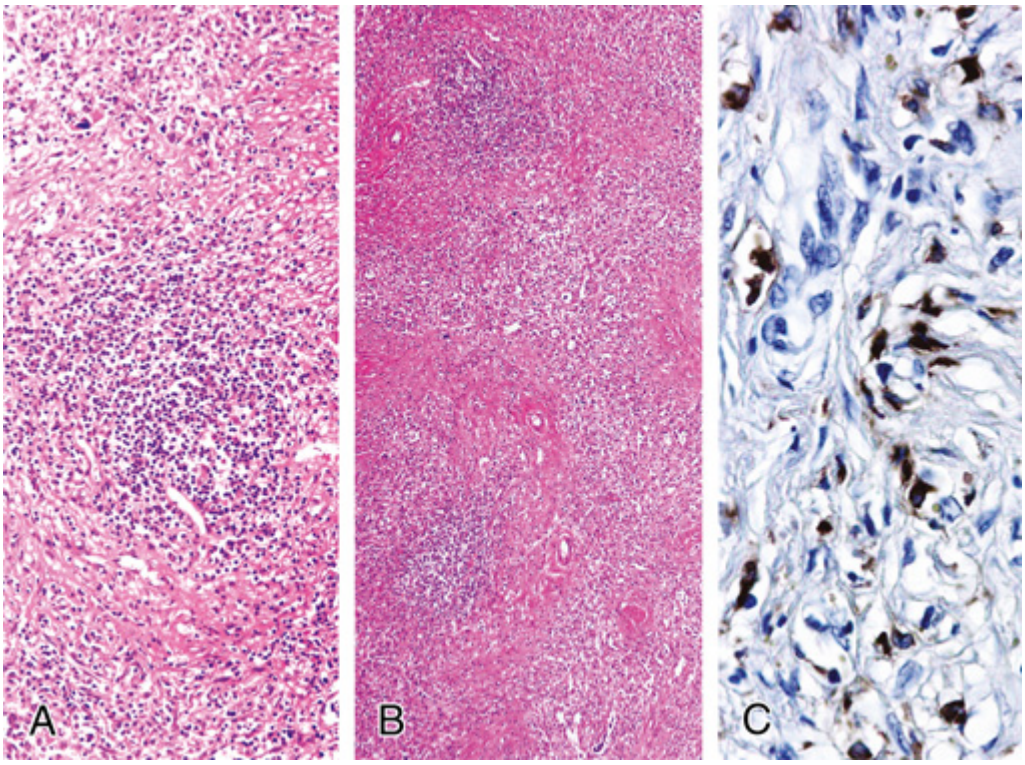

FIGURE 58-13 Systemic mastocytosis.**A,** Marked perifollicular fibrosis, with mast cells embedded in the fibrotic stroma. **B,** Perivascular, perifollicular, and trabecular fibrosis is often seen in mast cell disease in the spleen. **C,** Tryptase immunohistochemical stain highlights the mast cells entrapped in the sclerotic matrix.

Proliferations of the Monocyte-Macrophage System

A variety of histiocytic and dendritic cell tumors may involve the spleen but have features similar to involvement in other sites. These are described in **Chapters 51** and **52**.

Hemophagocytic Syndromes

The hemophagocytic syndromes (HPSs) are a group of systemic disorders characterized by acute-onset pancytopenia caused by a proliferation of macrophages in lymphoreticular organs associated with prominent phagocytosis of hematopoietic elements (**Box 58-2**).[105,106] A familial (primary) form of HPS affecting infants and young children is termed *familial hemophagocytic lymphohistiocytosis*.[107] It is inherited in an autosomal recessive manner and is caused by the overwhelming activation of T lymphocytes and macrophages associated with defective triggering of apoptosis and reduced cytotoxic activity. Mutations in a variety of genes, including perforin *(PRF1)*, have been found in patients with familial hemophagocytic lymphohistiocytosis.[106,107] Most secondary cases of HPS are related to either infection or an NK-cell or T-cell neoplasm, most often EBV positive. These cases were once thought to represent malignant histiocytosis because of the acute clinical course culminating in death in many cases; the systemic distribution; and the striking proliferation of cells in all lymphoreticular organs. They are characterized by a proliferation of benign histiocytes demonstrating prominent hemophagocytosis. Patients exhibit fever and varying cytopenias in a clinical context of underlying viral infection or malignancy.[108,109] Cases associated with infection have been referred to as either viral-associated or, later, infection-associated HPS.[108]

The spleen in infection-associated HPS is moderately to markedly enlarged. The red pulp shows a proliferation of macrophages that display prominent hemophagocytosis, most characteristically of erythrocytes, but also of granulocytes, lymphocytes, and platelets.

Fibrosis, focal infarctions, and gradual obliteration of the white pulp with B-cell depletion may occur.[5]

HPS-associated malignancies of the hematopoietic system differ morphologically because the spleen usually but not always contains a component of malignant cells. Lymphomas associated with HPS are most often of peripheral T-cell or NK-cell type.[109] Association with EBV is a major risk factor, and HPS is a common complication of extranodal NK/T-cell lymphoma, aggressive NK-cell leukemia, and systemic EBV-positive lymphoproliferative disease of childhood associated with chronic active EBV infection. When only rare neoplastic T cells are found admixed with the numerous histiocytes, the resemblance to malignant histiocytosis may be marked (**Fig. 58-14**). The diagnosis of T-cell lymphoma in these cases usually requires molecular confirmation.

Box 58-2 Disorders Associated With Hemophagocytosis in the Spleen

Benign

- Storage diseases
- Congenital hemophagocytic syndromes
- Viral infections (Epstein-Barr, other viruses)
- Other infections (bacterial, fungal, rickettsial, parasitic)
- Autoimmune hemolytic anemia
- Drug-induced (e.g., fludarabine)

Malignant

- Histiocytic sarcoma (malignant histiocytosis)
- Hepatosplenic T-cell lymphoma
- Other peripheral T-cell lymphomas
- B-cell lymphomas

Mesenchymal Tumors and Non-Neoplastic Disorders That Mimic Neoplasms

Vascular tumors are the most common tumors of the spleen (**Table 58-4**) that typically involve the red pulp. They may be diffuse or form a tumor mass and are usually found incidentally on imaging.[110]

Splenic Hemangioma

Splenic hemangiomas may be capillary or cavernous and have morphologic features similar to those observed elsewhere. They are benign tumors that are usually asymptomatic; however, some cause splenomegaly, abdominal pain, and hypersplenism.[111-116] Localized hemangiomas are most common and form single or multiple tumor nodules that contain cystic blood-filled spaces lined by endothelial cells. Papillary projections and thrombi may occur. Localized hemangiomas form nodules that are usually surrounded by fibrosis and may show calcification. Most radiographic procedures, including computed tomographic scans and sonograms, are non-specific, but show discrete solid and cystic masses, and often show evidence of calcification. Diffuse hemangiomatosis of the spleen, which is less common, is often associated with systemic hemangiomatosis. Cases with massive splenomegaly are often associated with coagulopathies.

Diffuse hemangiomatosis differs from peliosis by the presence of intervening fibrosis in hemangiomatosis, whereas more normal splenic tissue is present between the vascular spaces of peliosis. The differential diagnosis of hemangioma includes lymphangioma and primary splenic cyst; however, localized lymphangiomas and primary splenic cysts of the spleen usually contain proteinaceous fluid rather than the blood of a hemangioma. In addition, diffuse lymphangiomatosis may be localized to the spleen, but is usually a systemic process and most commonly occurs in children and young adults with massive splenomegaly.

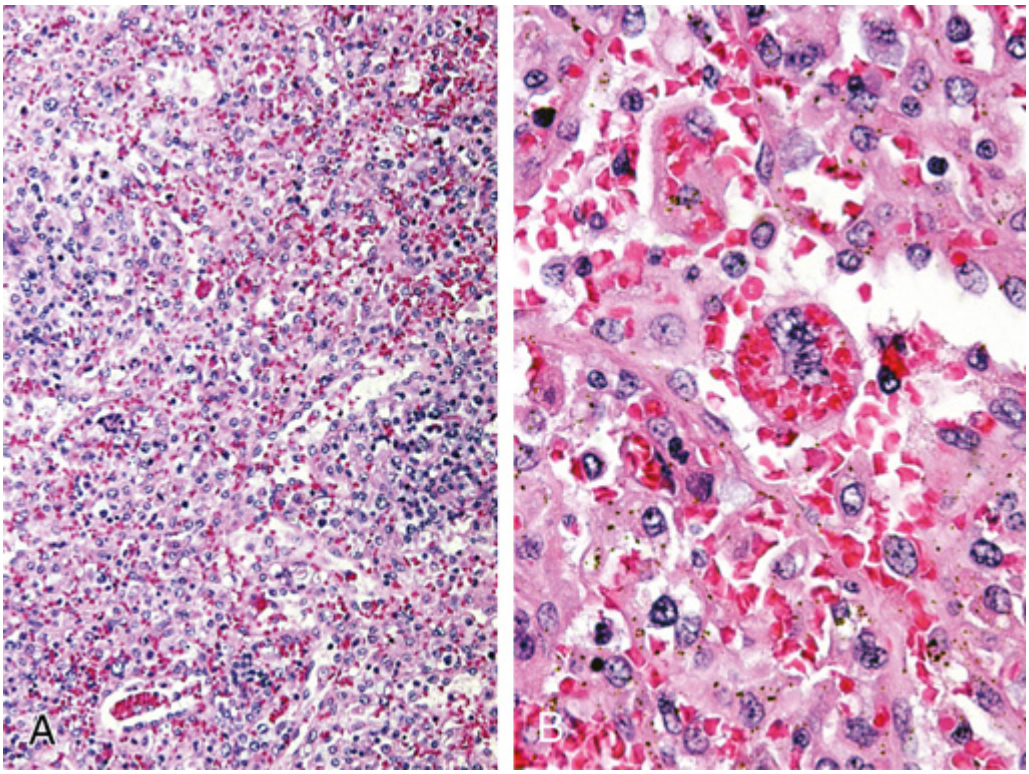

FIGURE 58-14 Peripheral T-cell lymphoma in the spleen associated with hemophagocytic syndrome.**A,** At low magnification, the findings are subtle. A variety of other disorders can be associated with hemophagocytosis in the spleen, most notably those with infectious or viral causes. **B,** Macrophage with ingested red blood cells *(center).* Also note the atypical-appearing lymphocytes, which proved to be T-cell lymphoma.

Table 58-4

EBV, Epstein-Barr virus; *SANT,* sclerosing angiomatoid nodular transformation.

Cord capillary hemangiomas are splenic capillary hemangiomas displaying a proliferation of small vessels associated with increased numbers of histiocytes and fibrosis. They form circumscribed nodules displaying a lobular pattern both grossly and histologically. They can be differentiated from other stromal proliferations by immunohistochemistry, highlighting the vascular nature of the lesion with expression of CD34, but not CD8.[117-119] This entity was first described by Krishnan and Frizzera[119] and was thought by these authors to represent a subtype of splenic hamartoma. More recently, however, clonality demonstrated in a few cases suggests that they represent true vascular tumors.[117]

Littoral Cell Angioma

Littoral cell angioma is a tumor that is unique to the spleen.[113,120] It may occur at any age and usually causes mild to moderate splenomegaly. As its name suggests, it is a tumor presumably derived from the littoral cells lining the sinus channels, but the tumor immunophenotype differs slightly from this presumed normal counterpart. Grossly, the spleen shows diffuse multinodularity with spongy, dark red nodules that can measure up to 9 cm in diameter. Rarely, it may present as a single, large mass. Histologically, the vascular spaces are lined by plump cells with nuclear enlargement and often show papillary areas with lining cells sloughing into the vascular spaces (**Fig. 58-15**). The lining cells of littoral cell angioma have a unique immunophenotype, expressing vascular, histiocytic, and dendritic-associated markers CD31, ERG, CD68, CD163, and at least focal CD21. Expression of Langerin and cyclin D1 have been described on the lining cells.[121] The actual lining cells are CD34

negative, and unlike normal splenic sinus lining cells, they do not express CD8. The differential diagnosis includes hemangioma and angiosarcoma. Hemangiomas of the spleen express CD34 and usually lack the nuclear enlargement of littoral cell angioma. Angiosarcomas show more cytologic atypia than littoral cell angiomas, as well as mitotic figures and necrosis, features that are not present in littoral cell angioma. Most cases of littoral cell angioma are treated with splenectomy without recurrence. Rare cases with foci containing a solid clear-cell proliferation have metastasized many years later, and such cases probably represent a rare controversial entity termed *littoral cell hemangioendothelioma*.[122,123] Other rare variants have also been reported (some are mostly pediatric).

Splenic Angiosarcoma

Splenic angiosarcoma is a rare tumor[113,124] that occurs most commonly in adults; fewer than 200 cases have been reported. It is usually associated with splenomegaly, abdominal pain, and cytopenias, and splenic rupture is seen in up to 30% of cases. Because most angiosarcomas involving the spleen are high-grade sarcomas with dissemination, it is often difficult to determine whether the splenic tumor is primary or secondary. The tumor typically forms a large infiltrating solid mass but can also form a network of anastomosing vascular channels (**Fig. 58-16**). Areas of cystic hemorrhage are sometimes present. Although the histologic appearance may be varied, angiosarcomas characteristically show atypical “hobnail” lining cells within vessels, high mitotic activity, and necrosis (**Fig. 58-17**). Many cases may be difficult to

differentiate from other high-grade sarcomas, and immunohistochemical detection of vascular antigen expression, such as CD31, CD34, ERG, FLI1, VEGF, and von Willebrand factor, is necessary to diagnose such cases. The differential diagnosis includes cavernous hemangioma, normal splenic sinuses, or other sarcomas, including Kaposi sarcoma. Immunostains for CD34, CD8, or HHV-8 can usually distinguish angiosarcoma from littoral cell angioma and Kaposi sarcoma, and the presence of necrosis or mitotic activity essentially excludes littoral cell angioma. High-grade angiosarcomas involving the spleen have a generally poor prognosis, and most patients die of disease within 1 year of diagnosis; however, rare cares with long-term survival after splenectomy are reported.

Splenic Lymphangioma

Lymphangiomas of the spleen are uncommon tumors that often present as an isolated nodule or diffusely throughout the spleen, often in the setting of a patient with lymphangiomatosis.[125,126] The localized tumors are subcapsular, whereas diffuse proliferations may involve the entire spleen. Three histologic categories are recognized: cystic, cavernous, and simple or capillary. Cystic lymphangiomas are most common and show thin-walled cysts of variable size filled with serous fluid. The endothelial cells are positive for CD31 and D2-40 and often focally positive for CD34, but negative for CD21 and CD68. These are benign lesions that often are found incidentally and require no treatment.

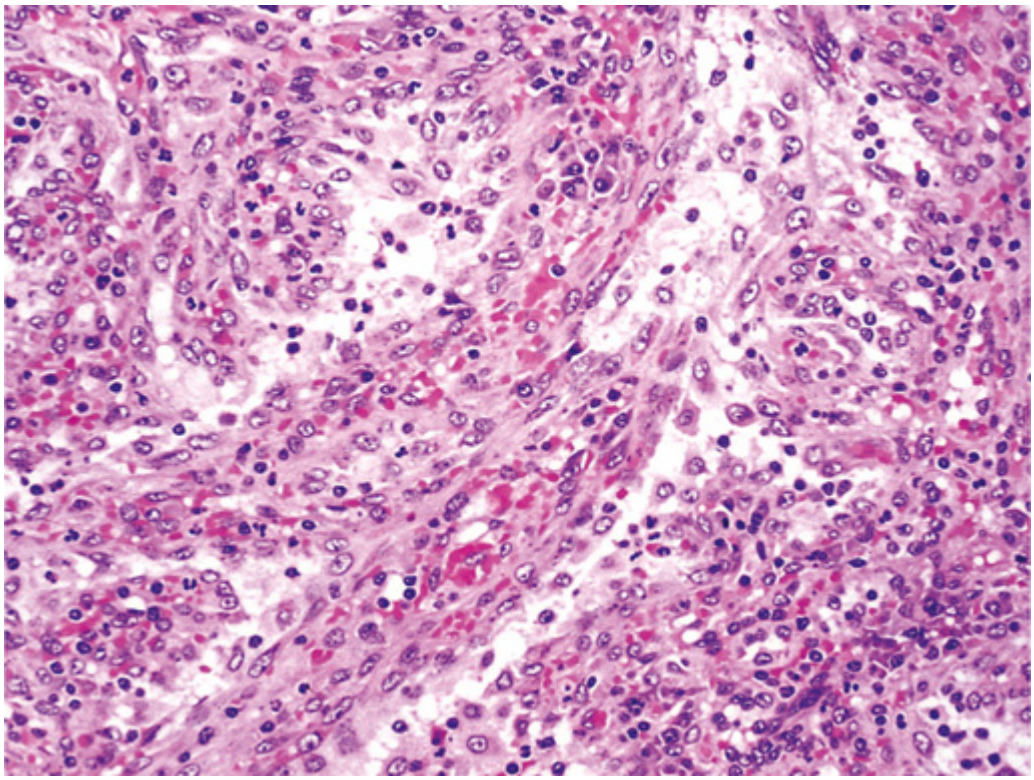

FIGURE 58-15 Littoral cell angioma with vascular spaces lined by plump endothelial cells lacking cytologic atypia. Sinus lining cells desquamate into the vascular lumens.

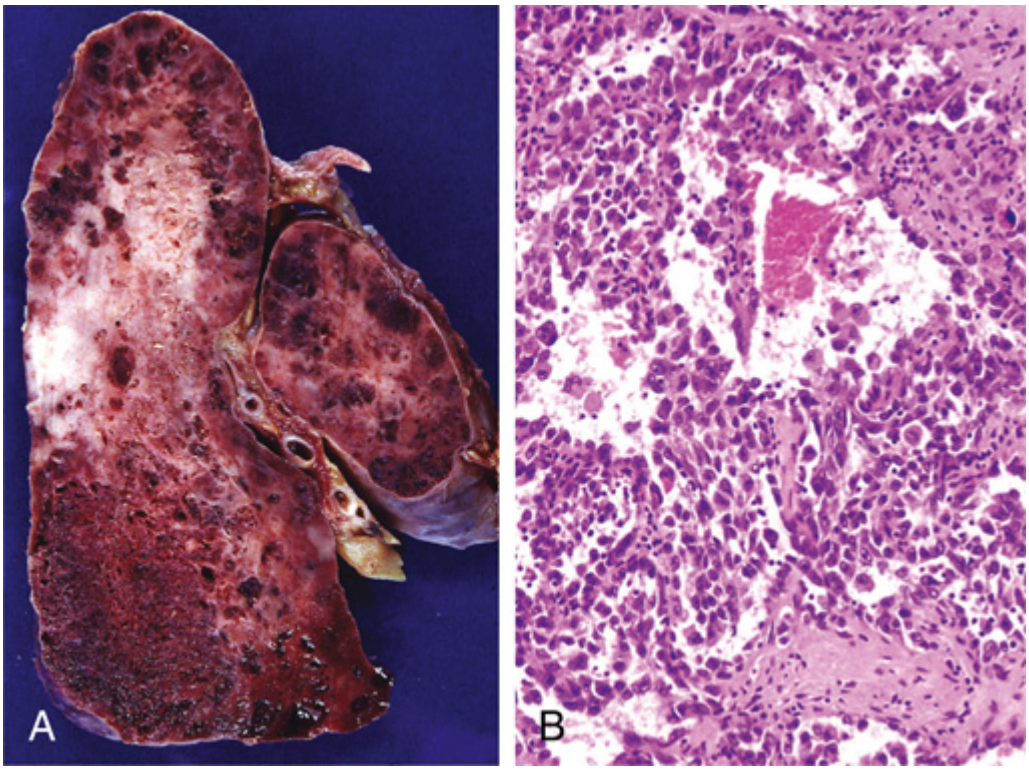

FIGURE 58-16 Gross **(A)** and microscopic **(B)** images of angiosarcoma of the spleen. Note the mixture of spongy, dark red cystic areas and more malignant-looking solid areas.

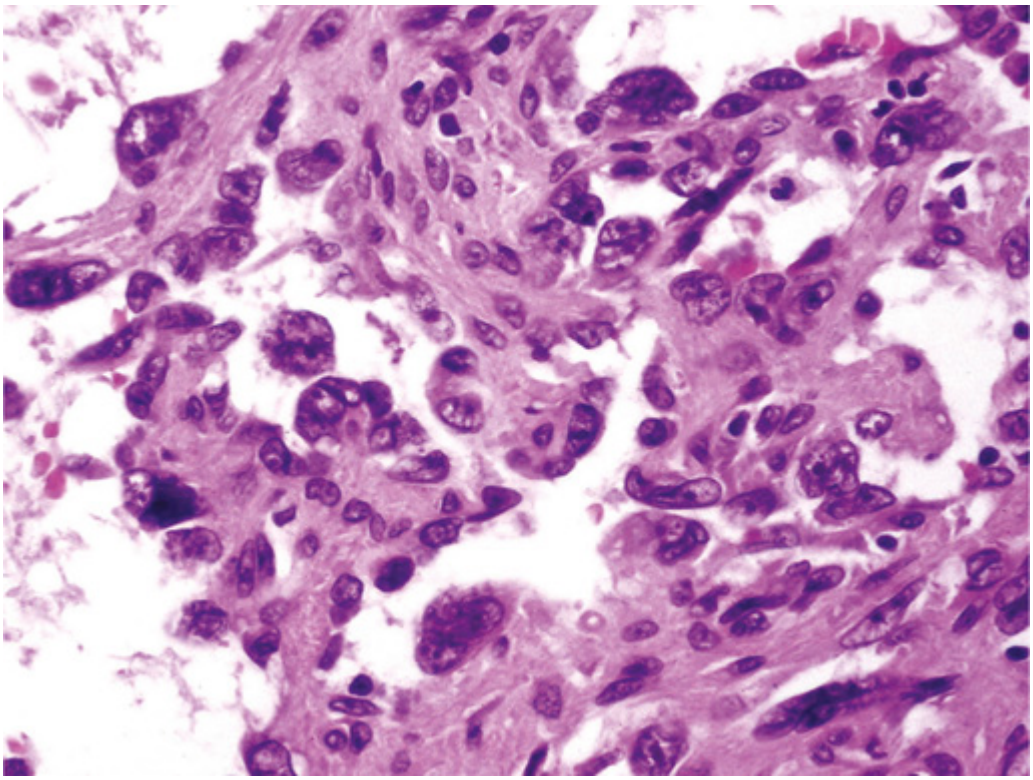

FIGURE 58-17 Photomicrograph of splenic angiosarcoma.The marked cellular pleomorphism is consistent with a diagnosis of angiosarcoma. Note the irregular, anastomosing appearance of the vascular channels.

Small, subcapsular cystic proliferations that are incidental findings in splenectomy specimens have been assumed to be localized lymphangiomas, but most are now known to have keratin-positive lining cells and represent small mesothelial primary cysts rather than lymphangiomas.[126]

Sclerosing Angiomatoid Nodular Transformation of the Spleen

Sclerosing angiomatoid nodular transformation (SANT) is a non-neoplastic vascular lesion of the spleen.[127-130] The median age at presentation is 54 years but ranges from 22 to 74 years. Most patients are asymptomatic, and a mass is only found incidentally; however, as many as 16% of patients complain of abdominal pain. A female predominance is seen with a female-to-male ratio of 2:1. A small subset of patients may have leukocytosis, an elevated erythrocyte sedimentation rate, and a polyclonal gammopathy.

The spleen is generally normal to slightly enlarged in size and on cut cross-section reveals a single red-tan, unencapsulated mass with a central stellate fibrous stroma and fibrous septa in areas surrounding multiple red-brown nodules. Although some nodules are outlined by densely collagenous fibrotic tissue, others are circumscribed by a fibrinoid rim that can give them a granulomatoid appearance (**Fig. 58-18**). Within the nodules, numerous slitlike round vascular spaces are seen that are lined by plump endothelial cells and pericytes. Rare mitoses can be seen, but cellular atypia should not be prominent. The fibrosclerotic internodular spaces are composed of myofibroblasts, and a mixed inflammatory infiltrate is commonly seen including lymphocytes, plasma cells, and macrophages.

The vessels of SANT show three staining patterns: a splenic sinusoidal immunophenotype with vessels lined by $CD34^{-}/CD31^{+}/CD8^{+}$ endothelial cells, a capillary-like immunophenotype with vessels lined by $CD34^{+}/CD31^{+}/CD8^{-}$ endothelial cells, and a venous immunophenotype with vessels lined by $CD34^{-}/CD31^{+}/CD8^{-}$ endothelial cells. CD68 expression within nodules can also be demonstrated. These staining patterns are

reminiscent of normal vasculature of red pulp vessels. The most sclerotic areas are often devoid of CD8-positive sinusoids. A background of scattered IgG4-positive plasma cells in the fibrosclerotic stroma is also seen.

The differential diagnosis of SANT includes other vascular lesions of the spleen, as well as nodular transformation of the splenic red pulp in response to metastatic carcinoma, and inflammatory pseudotumor. The nodular pattern with three different vessel types differentiates this proliferation from the others in the differential diagnosis. These proliferations are considered indolent, with no tendency for recurrence after splenectomy. Although many cases of SANT have admixed, IgG4-positive plasma cells,[130] SANT is not considered to be part of the spectrum of IgG4-related diseases.

Peliosis

Peliosis of the spleen is a rare proliferation of dilated blood-filled cavities.[131] Although it is more common in the liver, the spleen is occasionally a site of disease. Secondary conditions, such as infections, particularly tuberculosis; malignant conditions, such as lymphomas and leukemias; and drug use, as in chemotherapy, can be associated with peliosis. Sections of the spleen demonstrate multiple round-to-oval, blood-filled cysts with or without sinusoidal endothelial lining cells. Peliosis differs from hemangiomas or hemangiomatosis by the lack of intervening fibrosis. In peliosis, the dilated vascular spaces are separated by normal-appearing splenic red pulp and white pulp. Peliosis may be associated with spontaneous splenic rupture.

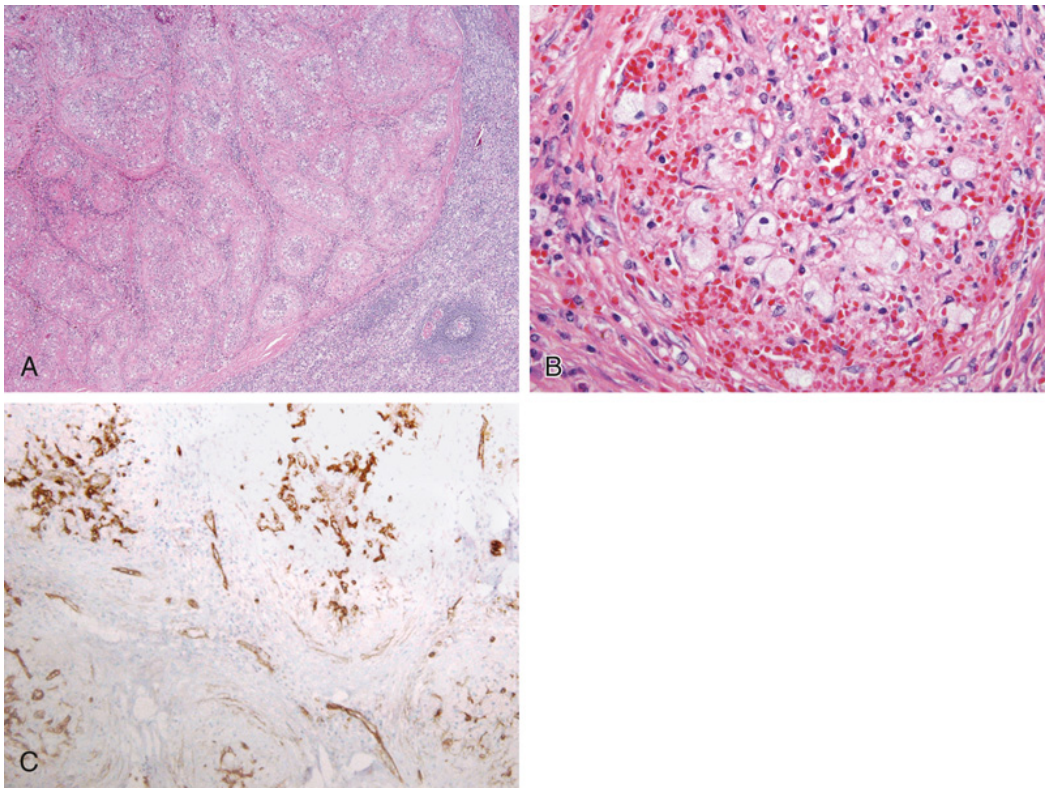

FIGURE 58-18 Sclerosing angiomatoid nodular transformation.**A,** The lesion is multinodular, with slitlike spacing surrounded by dense sclerosis. The gross appearance mimics inflammatory pseudotumor, but histologically, the distinction is usually not difficult. The lesion is sharply demarcated from adjacent spleen. **B,** Foam cells may be present in the nodules. **C,** The vascular slits within the nodules stain with CD34 and variably with CD31 and CD8 *(not shown)*.

Splenic Hamartoma

Hamartomas of the spleen are rare benign nodular lesions with an incidence of 0.13% and an equal occurrence in males and

females.[113,132,133] It appears most commonly in older adults, but up to 20% of cases can occur in children. Clinically, patients may present with splenomegaly, thrombocytopenia, or with other symptoms of hypersplenism; however, 50% of cases will be asymptomatic. These lesions are generally less than 3 cm in size but rarely reach up to 18 cm in size, and they form a red bulging tumor on cut sections of the gross spleen (**Fig. 58-19**). By histology, they are indistinct lesions that mimic normal red pulp. They show numerous slitlike vascular channels lined by plump to flattened endothelial cells, with an absence of normal red pulp cords, lymphatic elements, or organized white pulp elements. The cells lining the spaces show an immunophenotype of normal sinusoids, with expression of CD8 and CD31; CD34 expression is variable. These cells lack CD21 and CD68. The differential diagnosis includes inflammatory pseudotumor, SANT, and benign vascular tumors, capillary hemangioma in particular; however, the lack of a distinct tumor nodule on histologic sections is a distinctive and characteristic finding only seen in splenic hamartoma. Although most cases are benign in behavior, with large lesions, there can be a risk for rupture. Splenectomy is the most frequent treatment for symptomatic hamartoma.

Although most authors consider splenic hamartoma to represent what is described earlier, Krishnan and Frizzera proposed four subtypes of splenic hamartoma: the classical type, cord capillary hemangioma, myoid angioendothelioma, and histiocyte-rich type.[119] They propose that each subtype presents with a dominant expression of one or more components of the splenic red pulp. The cord capillary type differs from the classical hamartoma because of its

striking lobularity, bands of fibrosis, abundant plasma cells, and CD34-positive/CD8-negative phenotype of the vascular lining cells. This lesion may overlap with splenic capillary hemangioma with sclerosis. Clonality has been observed in some of these cases, which further suggests a true vascular origin for at least a subset of these cases.[117] The myoid angioendothelioma (originally described by Kraus and Dehner as benign vascular neoplasms of the spleen with myoid and angioendotheliomatous features) is a vascular lesion lined by CD34-positive cells, with prominent stromal cells positive for smooth muscle actin and muscle-specific actin.[134] The histiocyte-rich type has a predominance of histiocytes, including pseudosinuses lined by CD68-positive histiocytes, not endothelial cells. The latter two lesions are exceptionally rare. It is unclear whether the division into these subgroups has any clinical significance.

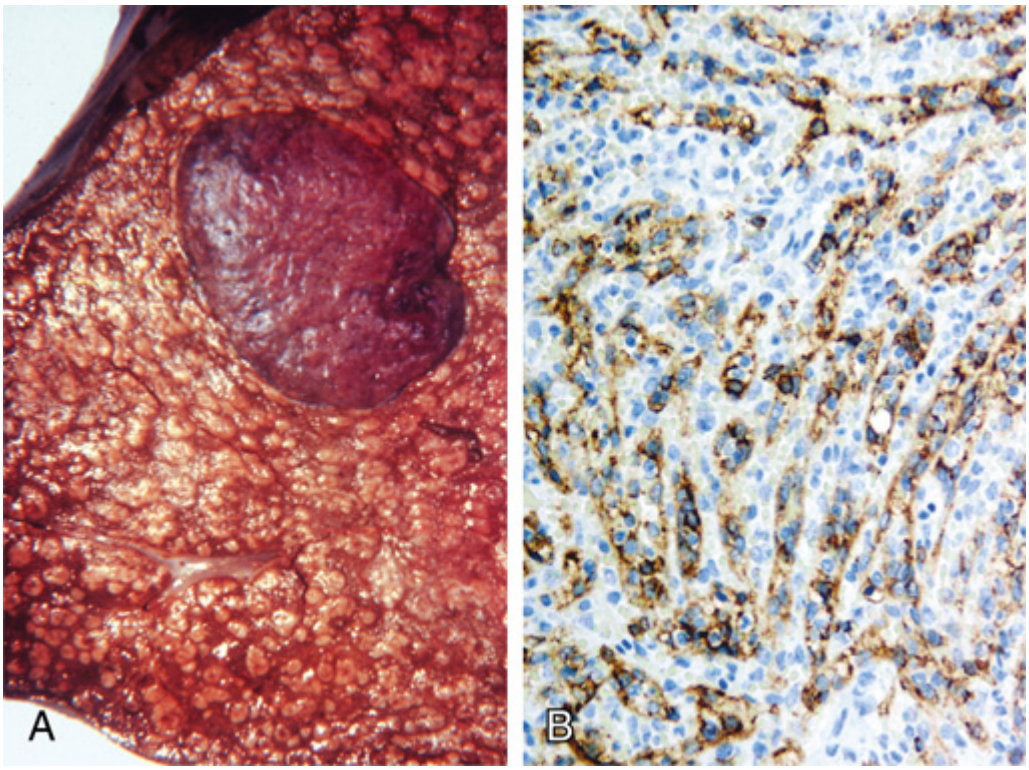

FIGURE 58-19 **A,** Gross photograph of a splenic hamartoma in a spleen removed for involvement by a low-grade B-cell lymphoma causing the background gross military pattern of infiltration. Note the well-circumscribed, bulging mass. The lesion consists of red pulp only and lacks white pulp. **B,** CD8 immunohistochemical stain highlights the splenic sinuses within the lesion.

EPSTEIN-BARR VIRUS—POSITIVE INFLAMMATORY FOLLICULAR DENDRITIC CELL/FIBROBLASTIC RETICULAR CELL TUMOR AND REACTIVE PSEUDOTUMORAL LESIONS OF THE SPLEEN

Epstein-Barr Virus–Positive Inflammatory Follicular Dendritic Cell/Fibroblastic Reticular Cell Tumor

Synonyms and Related Terms

WHO revised 4th ed.: Inflammatory Pseudotumor-Like Follicular/Fibroblastic Dendritic Cell Sarcoma

WHO proposed 5th ed.: EBV-Positive Inflammatory Follicular Dendritic Cell Sarcoma

Definition, Clinicopathologic Features, and Differential Diagnosis

Splenic and hepatic EBV-positive inflammatory follicular dendritic cell (FDC)/fibroblastic reticular cell (FRC) tumors (previously known as *inflammatory pseudotumor* or *inflammatory pseudotumor-like dendritic cell sarcoma*) are unique to these locations and differ from inflammatory pseudotumors or inflammatory myofibroblastic tumors at other sites.[135,136] They present predominantly in females as a fibroinflammatory process, often with fever and abdominal pain; a subset of cases are associated with a concomitant malignancy. The gross appearance of the spleen demonstrates a well-defined firm yellow-tan lesion without capsular extension; occasionally multiple

nodules are seen (**Fig. 58-20**). Histologically it appears as a bland spindle cell myofibroblastic proliferation with interspersed variable amounts of collagenous stroma, and intervening abundant inflammatory cells including lymphocytes, plasma cells, histiocytes, and eosinophils. Foci of necrosis may be seen. The spindle cells in some, but not all, tumors express CD21, with other FDC markers including clusterin, CD23, and CD35 being more inconsistent. Unlike inflammatory pseudotumors in other organs, the spindled cells in the spleen are positive for EBV, and may express vimentin and smooth muscle actin. The expression of smooth muscle actin may be indicative of a relationship to FRCs. Both FDCs and FRCs are mesenchymally derived stromal cells that may exhibit plasticity in their immunophenotype and function.[137] Thus, the spindle cells may express either FDC or FRC markers, but are always EBER positive. CD34 and CD8 are not expressed. All cases of EBV-positive inflammatory FDC/FRC tumor are negative for ALK1 in contrast to inflammatory myofibroblastic tumor of soft tissue, which is generally positive for ALK1. Splenectomy is curative for symptomatic cases, but cases that are partially resected may recur or rarely metastasize. Because most cases behave in a relatively indolent manner with resection, the International Consensus Classification (ICC) modified the name of this tumor to remove the “sarcoma” designation.[138]

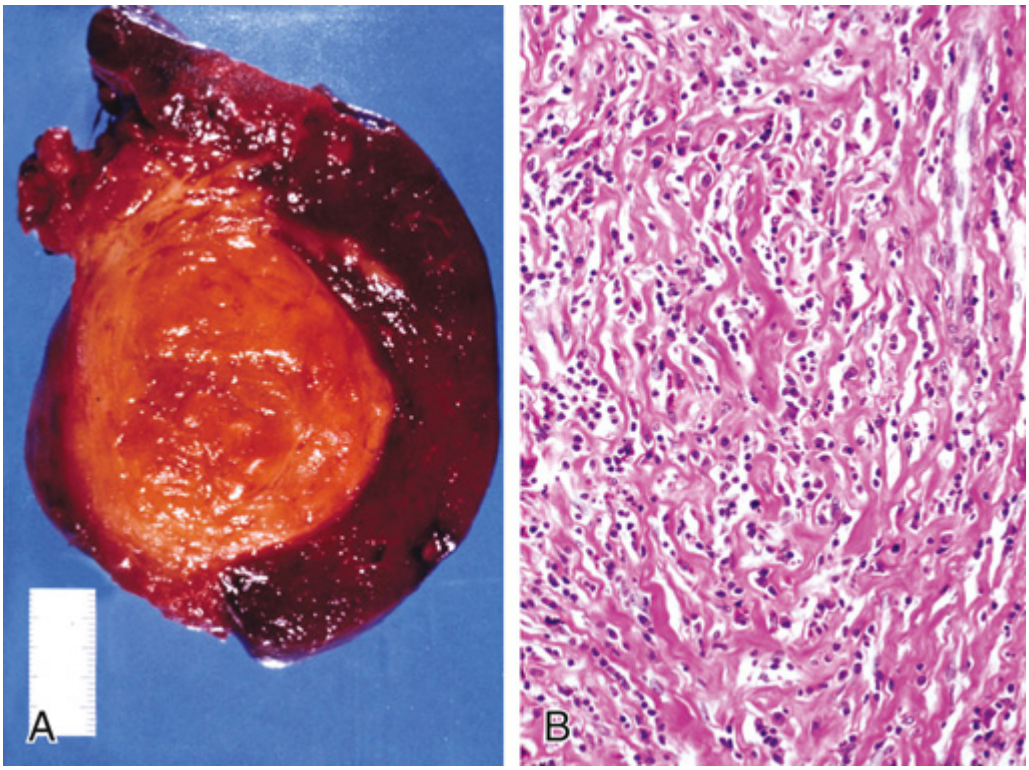

FIGURE 58-20 **A,** Gross photograph of an Epstein-Barr virus–positive inflammatory follicular dendritic cell/fibroblastic reticular cell tumor. The mass may mimic splenic involvement by a variety of malignancies, including Hodgkin and non-Hodgkin lymphomas. **B,** Microscopic appearance. This tumor has a predominance of fibrous bands, with a few spindle-shaped cells that are EBV positive *(not shown)*. Mixed inflammatory cells and spindle cells may be more prominent in other cases.

Non-specific areas of fibrosis may mimic inflammatory pseudotumor in the spleen. Because they are generally reactive proliferations, it is important to distinguish them from EBV-positive inflammatory FDC/FRC tumor, which is a true neoplasm that may

metastasize if not entirely resected. Areas of scarring after splenic infarction and hemorrhage (Gamna-Gandy bodies) are common in the spleens of children with sickle cell anemia, and fibrotic areas may occur after resolution of a splenic abscess or trauma.[139] SANTs often have areas of dense fibrosis with admixed (often IgG4-positive) plasma cells, but are EBV negative and do not contain FDC proliferations. Because of confusion caused by the term *inflammatory pseudotumor,* it is probably best to clarify that the reactive proliferations with fibrosis and inflammation are more inflammatory pseudotumor-like, with a clear statement that they do not represent a neoplastic proliferation.

Splenic Cysts

One of the most common benign proliferations of the spleen is the splenic cyst.[140-142] These tumors have a male predominance and typically present in the 3rd decade of life. They are designated as primary (true) or secondary (false). Primary cysts represent approximately 20% of all splenic cysts. They are unilocular and have a firm, fibrous, trabecular wall that is lined by mesothelial cells or squamous epithelium. Notably, the epithelial lining of primary cysts may be patchy, with denuded areas present that may simulate a secondary cyst. Primary cysts can be further subdivided into parasitic and nonparasitic types. Parasitic cysts, though uncommon, are typically attributable to *Echinococcus* and are readily identified by the presence of parasite scolices in the cyst contents. Nonparasitic primary cysts appear to arise from congenital inclusions of capsular mesothelium. Interestingly, patients with primary cysts may have elevations of CA19-9 and carcinoembryonic antigen (CEA).

Treatment in symptomatic cases requires a complete splenectomy, as incomplete resection often leads to recurrence. Secondary cysts represent approximately 80% of splenic cysts and are often associated with a history of abdominal trauma. These are unilocular and thin walled and differ from primary cysts by the complete absence of an epithelial lining and are thus unlikely to recur even if only partially resected.

Other Tumors

Primary sarcomas, other than angiosarcoma, and carcinomas of the spleen are extremely uncommon. Reported cases of sarcoma include malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdosarcoma, histiocytic sarcoma, interdigitating dendritic cell sarcoma, and FRC tumor.[141,143-149] Primary carcinomas reported include squamous cell carcinoma arising in a cyst, mucinous cystadenocarcinoma and carcinosarcoma, both possibly arising from peritoneal surface epithelium, and primary transitional cell carcinoma.[150-153] Although rare, carcinoma metastatic to the spleen or direct tumor extension are more common than primary disease. One-third of metastatic tumors are only identified on microscopic examination,[154] so the frequency of splenic involvement may be underestimated by imaging studies. Lung, gastric, ovarian, and breast carcinoma primaries are the most common to involve the spleen, and splenectomy may be performed for solitary splenic metastases.[155-157] Most metastases cause tumor masses, but some may infiltrate the organ diffusely (**Fig. 58-21**).

Storage Diseases

The spleen is involved in many of the lysosomal storage diseases. These are predominantly autosomal recessive conditions whose diagnosis and classification are based on the enzymatic defect characteristic of each disease, often in combination with specific genetic testing. Although most of these conditions are rare, three of the lipid storage diseases are encountered (uncommonly) in surgical pathology practice. Gaucher and Niemann-Pick diseases, particularly in their nonneuronopathic forms, are the most common storage diseases encountered in removed spleens.[5,158,159] The significant splenomegaly observed in these cases may cause hypersplenism. Not uncommonly in these cases, the spleen is removed to confirm the diagnosis or to ameliorate cytopenias. Ceroid histiocytosis (sea-blue histiocytosis) can also be observed. Accumulation of sea-blue histiocytes may be seen in association with lipid disorders, infectious diseases, red blood cell disorders, and myeloproliferative disorders. However, it is also a prominent feature in spleens removed from patients with Hermansky-Pudlak syndrome, a rare, often fatal autosomal recessive condition that is currently classified among the disorders of lysosome-related organelle biogenesis.[160]

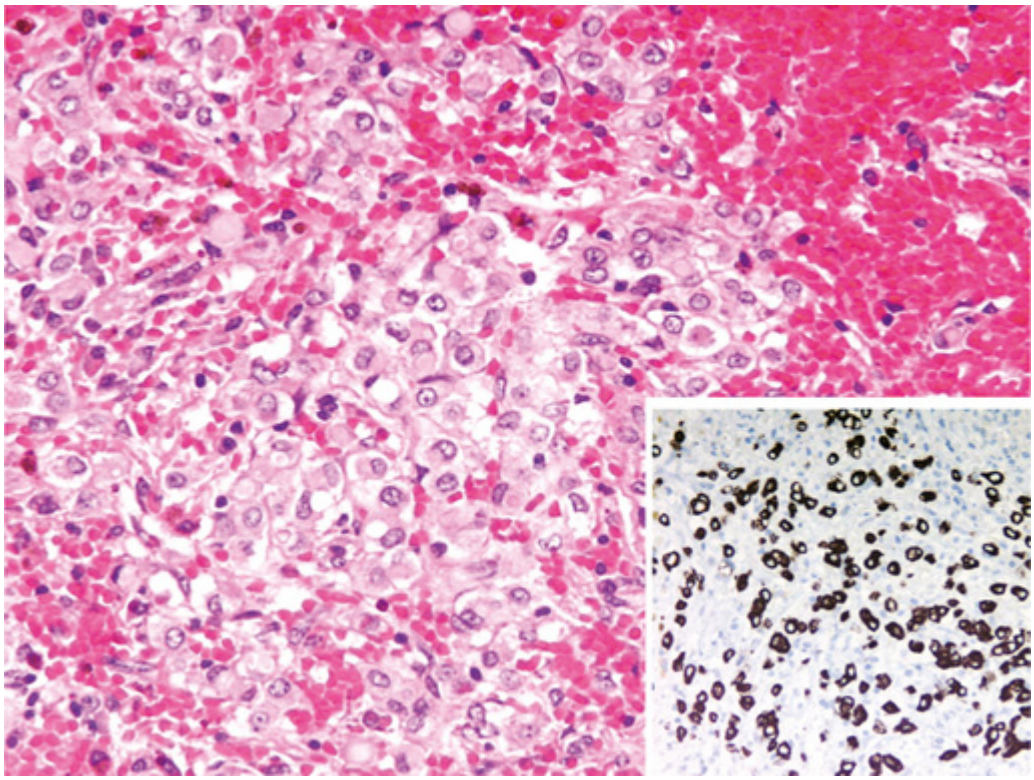

FIGURE 58-21 Signet ring carcinoma metastatic to the spleen.The malignant cells are strongly positive with a pan-cytokeratin immunostain *(inset)*.

In most storage disorders, affected spleens are usually pale and homogeneous in appearance. Rarely, areas of fibrosis are noted.[5] Microscopically, the red pulp is expanded because of the accumulation of numerous histiocytes in the splenic cords.[5]

Gaucher disease is the most common of the storage disorders. Gaucher cells range in size from 20 to 100 μm in diameter and have a fibrillar cytoplasm that appears brownish in hematoxylin and eosin (H&E)–stained preparations. Multinucleated cells may occur. The cytoplasm is intensely PAS positive, and this positivity is resistant to diastase digestion. The glucocerebroside in Gaucher cells is

autofluorescent. Because Gaucher cells are macrophages and ingest red blood cells, they frequently stain positive for iron. Lipid stains are only weakly positive. Ultrastructural studies reveal numerous lysosomes containing characteristic lipid bilayers. Pseudo–Gaucher cells are often seen in the spleens of patients with CML.

Niemann-Pick cells are large, ranging from 20 to 100 μm in diameter, and appear foamy or bubbly because of numerous small vacuoles. They are clearer than Gaucher cells and usually stain only faintly with periodic acid–Schiff stain, but they contain neutral fat, as demonstrated by Sudan black B and oil red O stains. The lipid deposits are birefringent and, under ultraviolet light, display yellow-green fluorescence. Electron microscopy reveals lamellated structures resembling myelin figures within lysosomes.

In cases of ceroid histiocytosis, smaller histiocytes with more basophilic cytoplasm and vacuoles are characteristically seen. These cells can also be seen in Niemann-Pick disease. Ceroid-containing histiocytes measure up to 20 μm and contain cytoplasmic granules that measure 3 to 4 μm. The histiocytes show a variable degree of granulation. Foamy histiocytes with smaller, darker granules may also occur. Ceroid is composed of phospholipids and glycosphingolipids and is similar to lipofuscin in its physical and chemical properties. Histiocytes containing ceroid appear faintly yellow-brown in H&E–stained sections, but blue-green with Romanowsky stains, resulting in the term *sea-blue histiocyte*. Ceroid is PAS-positive and resistant to diastase digestion and stains positive for lipid. It shows a strong affinity for basic dyes such as fuchsin and methylene blue. Ceroid is acid-fast and becomes autofluorescent

with aging of the pigment. Ultrastructural studies reveal inclusions of lamellated membranous material with 4.5- to 5-nm periodicity.

None of the cell types identified in storage disorders is specific for a given disease, and their actual diagnosis should be based on biochemical or molecular genetic testing specific for these diseases.

Pearls and Pitfalls

- The most common primary splenic lymphomas—splenic marginal zone lymphoma and hepatosplenic T-cell lymphoma—tend to present with splenomegaly without peripheral lymphadenopathy and typically involve the bone marrow.
- Myeloid hyperplasia in the red pulp, which can mimic acute myeloid leukemia, may be caused by cytokines, particularly granulocyte colony-stimulating factor.
- Splenic hamartoma has distinct borders on gross examination, but the border of the lesion may be difficult to identify on microscopic examination.
- Littoral cell angioma has large lining cells with enlarged nucleoli, but fails to demonstrate mitotic activity or necrosis.
- Epstein-Barr virus (EBV)–positive inflammatory follicular dendritic cell/fibroblastic reticular cell tumor may mimic a reactive proliferation; extensive immunohistologic panels are usually necessary, as well as in situ hybridization for EBV.

- Careful interpretation of CD8, CD31, and CD34 stains is useful in assessing splenic vascular lesions (e.g., endothelial cells in hamartoma are CD8 positive).

Chapter 59: Diagnosis of Lymphoma in Extranodal Sites Other Than Skin

Judith A. Ferry

OUTLINE

- Lymphomas of Immune-Privileged Sites
- Lymphoma of The Nervous System and Meninges
  - Primary Central Nervous System Lymphoma
  - Vitreoretinal Lymphoma
  - Lymphoma of the Dura Mater
- Ocular Adnexal Lymphoma
  - Clinical Features
  - Pathologic Features
  - Staging, Treatment, and Outcome
  - Differential Diagnosis
- Lymphomas of Waldeyer's Ring

Clinical Features

Pathologic Features

The types of lymphoma encountered in extranodal sites differ from those encountered in lymph nodes. Many of the lymphomas that may involve extranodal sites are described as specific pathologic entities in other chapters. In this chapter, emphasis is placed on the types of lymphomas encountered in different extranodal sites, and on site-specific differences in clinical and pathologic features among these lymphomas.

Lymphomas of Immune-Privileged Sites

Certain anatomic sites, including the central nervous system (CNS), the eyes, and the testes, are considered immune-privileged sites. Almost all of the lymphomas that arise in these sites are diffuse large B-cell lymphomas (DLBCLs) that share distinctive features: they almost all occur in adults over age 60, are characteristically Epstein-Barr virus (EBV)–negative DLBCLs with an activated B-cell immunophenotype, tend to spread to other immune-privileged sites, frequently have mutations of *MYD88* and *CD79B,* and frequently have genetic changes leading to immune evasion (inactivation of major histocompatibility complex [MHC] class I and II and β2 microglobulin).[1] They typically have a characteristic genomic signature by high-throughput sequencing (HTS), which has been variously designated as C5/MCD.[2] These cases were segregated under the above designation by the World Health Organization

(WHO) 5th ed.[1] The International Consensus Classification (ICC) similarly identified the special features of primary DLBCL of the CNS and testis, segregating them from other subtypes of DBLCL.[3] However, the ICC deferred creation of this nosologic category, as the full scope of such cases is yet to be defined. For example, a subset of DLBCL of the breast and primary cutaneous DLBCL may share similar pathologic features.[4] Thus, it is likely that this designation may evolve over time.[1-4]

Lymphoma of The Nervous System and Meninges

Primary Central Nervous System Lymphoma

Primary central nervous system lymphoma (PCNSL, almost all of which are DLBCLs) is defined as lymphoma confined to the CNS (brain, spinal cord, or leptomeninges) at presentation.[5] Vitreoretinal lymphoma (VRL) is closely related to PCNSL and, in the absence of prior or concurrent lymphoma outside the CNS, it is considered a subset of PCNSL (**Table 59-1**). VRL is considered separately.

Epidemiology and Etiology

Lymphoma may arise in the CNS in either immunocompetent patients or immunosuppressed patients. Those developing in immunocompromised patients are classified separately as *immunodeficiency-associated CNS lymphomas*.[6] Among immunocompetent patients, PCNSL makes up 1.5% to 3% of all brain tumors, 4% to 6% of all extranodal lymphomas, and 1% of all non-Hodgkin lymphomas.[7,8] PCNSL can occur at any age, but patients are predominantly older adults (median age, 55 to 66 years) with a male-to-female ratio of 3:2.[7,9-13]

Clinical Features

Symptoms are usually of short duration, and depending on the site of the lesion, include cognitive dysfunction, psychomotor slowing, speech disturbances, vertigo, weakness, hypothalamic dysfunction, ocular abnormalities, or disturbances of mobility such as ataxia, hemiparesis, hemiplegia, or abnormal gait. Patients may also have

seizures or evidence of increased intracranial pressure such as headache, papilledema, nausea, or vomiting. Some present with personality changes, confusion, or dementia, mimicking a non-neoplastic disorder.[7,10,12,14,15] If the meninges are involved, symptoms related to cranial nerves may be seen.[7]

PCNSL usually presents as a supratentorial mass; cerebellar presentation is unusual and spinal cord presentation is rare. In immunocompetent patients, lesions are usually single. Though PCNSL in the brain or spinal cord may involve the leptomeninges secondarily, PCNSL rarely arises in the leptomeninges. The most common sites are the frontal, temporal, and parietal lobes, thalamus, basal ganglia, and corpus callosum. Presentation in the pituitary is rare (**Fig. 59-1**).[16] Lesions are often periventricular, so that cerebrospinal fluid (CSF) seeding may occur.[7,9,16-18] Imaging typically shows irregular, contrast-enhancing lesions with central hypodense areas, consistent with necrosis.[7]

Diagnosis is best established by stereotactic biopsy of the tumor. CSF for cytologic examination is relatively insensitive. Resection of the tumor does not improve survival and may lead to a greater neurologic deficit.[10,11,17]

Morphologic Features

Gross examination shows poorly circumscribed masses with replacement or displacement of normal structures, often with areas of necrosis or hemorrhage. Some patients have diffuse meningeal involvement resembling meningitis or, rarely, diffuse subependymal periventricular involvement by tumor.[19]

Table 59-1

ALCL, Anaplastic large cell lymphoma; *BCL,* B-cell lymphoma; *BL,* Burkitt lymphoma; *CNS,* central nervous system; *DLBCL,* diffuse large B-cell lymphoma; *EATL,* enteropathy-associated T-cell lymphoma; *EBV,* Epstein-Barr virus; *EMZL,* extranodal marginal zone lymphoma; *GI,* gastrointestinal; *IPSID,* immunoproliferative small intestinal disease; *MEITL,* monomorphic epitheliotropic T-cell lymphoma; *NK,* natural killer; *TCL,* T-cell lymphoma.

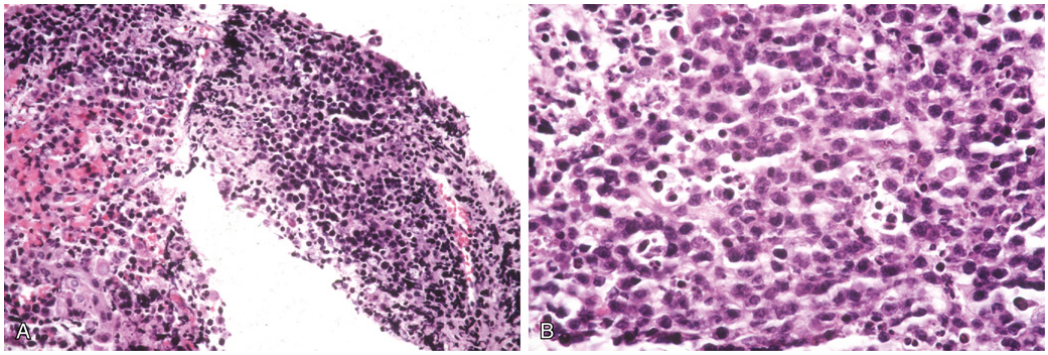

FIGURE 59-1 Diffuse large B-cell lymphoma, arising in the area of the pituitary.A, The biopsy fragments show a dense, diffuse lymphoid infiltrate, with a few residual bright red anterior pituitary parenchymal cells. **B,** High power shows large, atypical cells with interspersed tingible body macrophages.

The vast majority are DLBCLs. The characteristic microscopic appearance is a diffuse proliferation of centroblasts or immunoblasts, with peripheral areas of perivascular growth and,

often, necrosis.[5,19] If steroids have been administered before biopsy, neoplastic cells may undergo extensive apoptosis and the tumor may temporarily shrink or even disappear, hindering diagnosis. The remainder are low-grade B-cell lymphomas sometimes classified as extranodal marginal zone lymphoma (EMZL),[20] Burkitt lymphoma (BL), and peripheral T-cell lymphoma, including rare cases of anaplastic large cell lymphoma.[21,22] Also, 1% to 2% of cases are intravascular large B-cell lymphoma.[7,19]

Immunophenotype

The DLBCLs express pan-B cell antigens and monotypic immunoglobulin (usually IgM, IgD).[7,23] They almost always have a non-GCB immunophenotype ($CD10^-$, $BCL6^{+/-}$, $MUM1^+$).[24]

Genetic Features

Molecular genetic analysis shows monoclonal immunoglobulin gene rearrangements in DLBCL.[12,25] EBV is almost always negative, except in the setting of immune deficiency.[9,25] There is preferential use of certain VH families, as well as a high load of somatic mutations, in some cases accompanied by ongoing somatic hypermutation. Aberrant somatic hypermutation of genes that include *BCL6, BCL2, MYC, PAX5,* and others is common. Translocations involving immunoglobulin genes, BCL6, and ETV6 are frequent,[5,26] while translocations of *MYC* and *BCL2* are rare to absent.[5,26] Gains of genetic material are common, most often affecting 18q21-q23 (including *BCL2* and *MALT1*).[27] Losses of genetic material are also common; they most often involve chromosomal material at 6q21, 6p21 (including HLA class II–encoding *HLA-DRB, HLA-DQA,* and *HLA-DQB*), and 8q12.1-q12.2.[27]

Accordingly, loss of expression of HLA proteins is common[28] and likely contributes to survival of the neoplastic cells through immune escape.[28,29] *CDKN2A* deletions, often biallelic, are common.[30,31]

The B-cell receptor, toll-like receptor, and NF-κB pathways are often activated because of mutations involving *MYD88* (MYD88 L265P, found in the majority of cases), *CD79B, PIM1, CDKN2A, INPP5D, CARD11, MALT1,* and *BCL2,* which promote proliferation and cell survival.[27,30-35] Gene-expression profiling typically shows activated B-cell (ABC) DLBCL.[34,35]

Epigenetic changes likely also contribute to pathogenesis. Hypermethylation of *DAPK1, CDKN2A,* and *MGMT* are each seen in the majority of cases.[5,36] Neoplastic cells are believed to correspond to antigen-selected late germinal-center exit B cells.[5,12,23]

Staging, Treatment, and Outcome

Staging should be performed to exclude systemic lymphoma with secondary CNS involvement.[7] Primary CNS DLBCL is an aggressive neoplasm requiring prompt diagnosis and therapy.[23] Survival is only a few months without therapy. Therapy for PCNSL in years past was whole-brain radiation combined with steroids. This resulted in a complete remission in 90% of cases, but the lymphoma usually relapsed within a year, with a median survival of 12 to 18 months and 5-year survival of 3% to 4%.[10,11,17] More recently, therapy using methotrexate, an agent able to penetrate the blood-brain barrier, has improved survival.

Relapses usually involve the CNS. In a few cases, lymphoma spreads outside the CNS; these sites are usually extranodal, with frequent testicular involvement.[11] The prognosis is better for

immunocompetent patients who are younger than 60 to 65 years.[10,11,14] The low-grade B-cell lymphomas have a relatively favorable prognosis.[9,19,20]

Differential Diagnosis

Sampling artifact or prior steroid therapy can result in a biopsy showing a predominance of small reactive T cells, mimicking a chronic inflammatory process.[5] Avoiding prebiopsy steroids and obtaining intraoperative frozen sections to be certain that tissue is representative in any case of suspected PCNSL are helpful in establishing a diagnosis. There may be a surrounding glial reaction that may mimic glioma. Other neoplasms, including small round cell tumors, undifferentiated carcinoma, melanoma, and certain gliomas can grow in sheets and mimic lymphoma.[19] Vasculitis can mimic areas of lymphoma with perivascular growth.

Immunodeficiency-Associated Central Nervous System Lymphomas

Immunologic abnormalities are important in the pathogenesis of a subset of CNS lymphomas.[6] Immunodeficient patients who develop PCNSL are mostly HIV positive, with risk previously estimated as high as 1000× that of immunocompetent individuals.[25] These patients are overall younger, with a prominent male preponderance. There is also an increased incidence of PCNSL with iatrogenic and congenital immunodeficiency. The increased risk posttransplant was seen mainly in older azathioprine-based regimens[37] and is much less with more recent regimens. The introduction of highly active antiretroviral therapy (HAART) for HIV-positive patients dramatically decreased the occurrence of PCNSL in this group.[38]

Virtually all PCNSL in immunocompromised patients are EBV-positive DLBCL.[7,9,10,17,19,23,25] In contrast to the genetic changes seen in PCNSL in immunocompetent patients, EBV-positive PCNSL in immunodeficient patients typically harbors wild-type *MYD88, CD79B,* and *PIM1* with a lower overall mutational burden, and also show different microenvironmental features, indicating striking differences in pathogenesis.[34,35]

Vitreoretinal Lymphoma

Clinical Features

VRL, also called *ocular lymphoma* or *intraocular lymphoma*—lymphoma of the eye itself—is uncommon.[39-41] It predominantly affects older adults,[42] although occasionally young adults[43] and, rarely, children[44] are affected. There is a female preponderance.[39,45] Most patients have no known predisposing conditions, but VRL has been described in HIV-infected patients[41] and in iatrogenically immunosuppressed allograft recipients.[40,44] As for PCNSL, these would be classified separately, as immunodeficiency-associated lymphomas.

Patients typically have decreased visual acuity, floating spots, or both.[46] Although symptoms are often unilateral, examination reveals bilateral involvement in about 80% of cases.[39] VRL arises beneath the retinal pigment epithelium (RPE) and above the Bruch membrane, and subsequently infiltrates the neuroretina, optic nerve head, and vitreous.[47-49] Whitish, yellow-white, or gray-white infiltrates or large masses may be seen beneath the RPE, in the uvea, suspended in the vitreous or invading the optic nerve, sometimes with edema, hemorrhage, necrosis, or retinal detachment. Other

manifestations include increased intraocular pressure, keratic precipitates (deposits of cells on the posterior surface of the cornea), and anterior chamber cells and flare (presence of increased protein causing the normally clear fluid of the anterior chamber to become cloudy [flare] with tiny particles [cells] suspended in the fluid).[39,50]

VRL can mimic non-neoplastic conditions, including chronic idiopathic uveitis, retinal vasculitis, optic neuritis, amyloidosis, sarcoidosis, and infections, including toxoplasmosis, syphilis, tuberculosis, Whipple disease, and cytomegaloviral infection.[39] Poor response to steroids or antimicrobial therapy or onset of neurologic symptoms caused by CNS involvement can suggest lymphoma.[39]

Techniques used to establish a diagnosis include vitreous aspirate, vitrectomy, biopsy, or in patients with a blind, painful eye, ocular enucleation. The mode most commonly used is microscopic examination of vitreous, but the sensitivity of this procedure may be limited by admixed inflammatory cells or by prior steroid therapy, which may eliminate many tumor cells. Diagnostic yield may be improved by combining routine light microscopy with flow cytometry and molecular genetic analysis.[51] An elevated IL-10 level in the vitreous is strongly associated with VRL and could prompt rebiopsy if the initial specimen is nondiagnostic.[39]

Pathologic Features

Nearly all VRL are DLBCL.[41] Their morphologic, immunophenotypic, and genetic features are similar to primary CNS DLBCL.[52-54] DLBCL of nongerminal-center B-cell type (non-GCB) is more common than GCB type.[46] Rare cases of peripheral T-cell

lymphoma presenting with ocular involvement have also been described.[43,45,55]

Staging, Treatment, and Outcome

Most VRL are associated with CNS lymphoma either at presentation or, without treatment, on follow-up; a minority are associated with systemic lymphoma or remain confined to the eye. Aggressive treatment of isolated VRL can decrease the risk of progression.[39,56]

VRL frequently responds to radiation therapy, but restoration of sight is not guaranteed, because the retina may already be irreversibly damaged and because radiation may be associated with retinopathy and cataracts. Patients treated with ocular radiation alone often develop ocular recurrence or progress to CNS or, less often, systemic involvement. Other therapeutic considerations include combined chemotherapy and radiation, chemotherapy alone, intensive chemotherapy with autologous stem cell transplant and intravitreal methotrexate. On follow-up, most patients are alive with lymphoma or succumb to lymphoma.[46]

Lymphoma of the Dura Mater

Clinical Features

Lymphoma arising in the dura mater is uncommon. Patients are mostly middle-aged and older adults. There are no known risk factors. They present with seizures, headache, cranial nerve abnormalities, radicular pain, syncope, or a combination of these findings.[57-61] Radiologic evaluation usually reveals a localized, expansile mass or plaque-like thickening of the dura over the brain[59,62,63] that is most often thought to be a meningioma or, less

often, a nerve sheath tumor or a subdural hematoma preoperatively.[58,59]

Pathologic Features

Approximately half of cases are diffuse large cell lymphomas (B lineage when immunophenotyped). The remainder are mostly EMZLs of mucosa-associated lymphoid tissue.[59,61] EMZLs have histologic and immunohistologic features similar to those seen in other sites. They are composed of small lymphocytes and marginal zone cells, usually with prominent plasmacytic differentiation and admixed reactive follicles (**Fig. 59-2**).[20] An increased proportion of dural EMZLs contain monotypic plasma cells expressing IgG4,[64] although without evidence of associated IgG4-related disease. Entrapped meningothelial cells may be seen.[58,59,61] Dural EMZLs may arise in association with meningothelium, just as EMZLs often arise in association with epithelium in other sites.[58,59] Dural lymphomas are typically localized. The prognosis is excellent.[58,59,61]

Differential Diagnosis

Other low-grade B-cell lymphomas, such as lymphoplasmacytic lymphoma and chronic lymphocytic leukemia, can have histologic features mimicking EMZL, but the immunophenotype and localized nature of the lymphoma exclude other low-grade lymphomas. Some cases previously interpreted as dural plasmacytoma may represent EMZL with marked plasmacytic differentiation.[58,59] Some cases may raise the question of inflammatory pseudotumor or a chronic inflammatory process or lymphoplasmacyte-rich meningioma, but immunophenotyping or genotyping can help establish a diagnosis.

Ocular Adnexal Lymphoma

Clinical Features

Primary ocular adnexal lymphoma is defined as lymphoma arising in orbital soft tissue, lacrimal gland, conjunctiva, or eyelids. The orbital soft tissue is the most common site, followed by the conjunctiva, the lacrimal gland, and then the eyelids.[65,66] The ocular adnexa is where 1% to 2% of all lymphomas[67] and approximately 8% of all extranodal lymphomas[68] arise. Lymphoid tumors compose 10% of orbital mass lesions, and lymphoma is the most common orbital malignancy.[67] Lymphomas in this site predominantly affect older women (M:F = 3:4) with a median age in the 60s.[69] Children are only rarely affected.[69] Occasionally, patients have a history of an autoimmune disorder,[69,70] another malignancy,[71] HIV infection,[70,72] or contact lens wear.[73] Some ocular adnexal lymphomas are associated with *Chlamydia psittaci* infection; a subset of lymphomas in such patients responds to antibiotic therapy.[74] However, this association has not been confirmed in other series, which may reflect geographic variation.[75]

Patients present with proptosis, ptosis, a palpable or visible mass, diplopia, limitation of movement, tearing, or discomfort.[69,70] High-grade lymphomas occasionally cause a rapid decrease in visual acuity.[46] Systemic symptoms are rare. Conjunctival lymphoma usually produces a salmon-colored plaque that is mobile over the surface of the eye. The orbital soft tissue is involved in the majority of cases, sometimes accompanied by lacrimal gland involvement. The conjunctiva is involved in up to approximately one-third of cases.[69] In 10% to 25% of cases,[69,76,77] there is bilateral involvement.

Pathologic Features

Lymphomas of many types can present with ocular adnexal involvement, but nearly all are B-cell lymphomas. Most (60%–75%) are EMZLs.[69,70,78,79] Most of the remainder are follicular lymphomas (FLs), followed by DLBCL. The DLBCLs are of GCB and non-GCB types, in roughly equal numbers.[46] Few cases of mantle cell lymphoma and rare cases of chronic lymphocytic leukemia, lymphoplasmacytic lymphoma, BL, plasmablastic lymphoma, and B lymphoblastic lymphoma present with ocular adnexal involvement.[69,80] The few primary ocular adnexal lymphomas encountered in children or in HIV-positive patients are usually high-grade B-cell lymphomas, either DLBCL or BL.[81,82] Rare cases of T-cell lymphoma and NK-cell lymphoma[69,70,79] have had ocular adnexal involvement at presentation. Hodgkin lymphoma is vanishingly rare.[70]

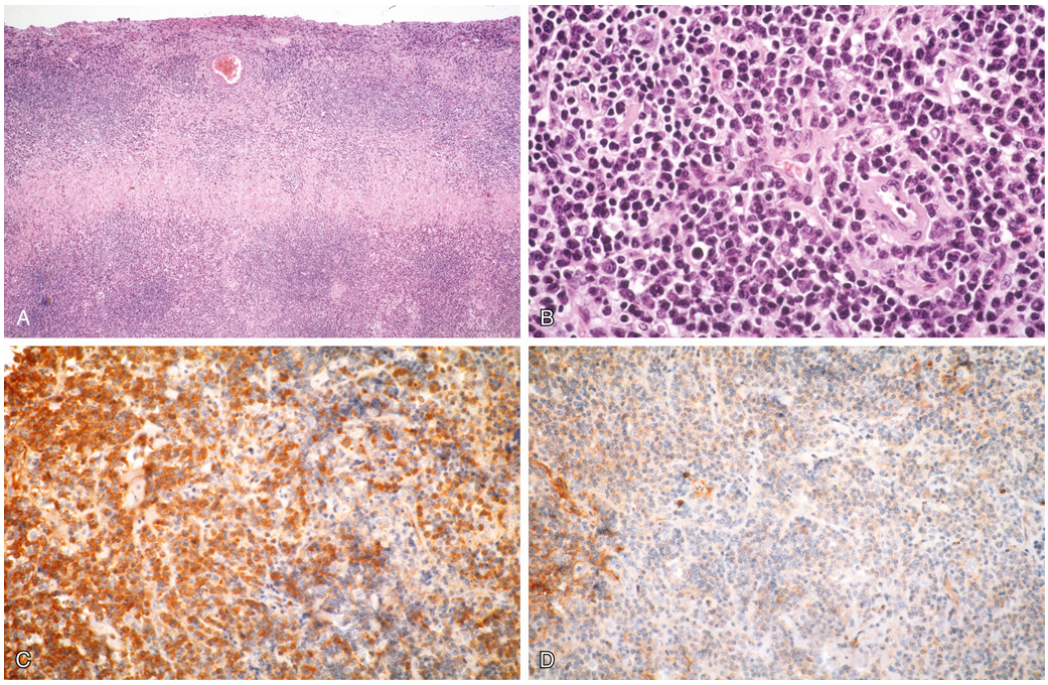

FIGURE 59-2 Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, dura mater.A, The dura shows a dense lymphoid infiltrate. **B,** Higher power shows small lymphoid cells and aggregates of plasma cells. **C,** Plasma cells express monotypic cytoplasmic kappa light chain (immunoperoxidase technique on paraffin sections). **D,** Staining for cytoplasmic lambda light chain is negative (immunoperoxidase technique on paraffin sections).

The immunophenotypic and genetic features are overall similar to those of the same types of lymphomas arising in other anatomic sites, although ocular adnexal EMZL shows a tendency for site-specific genetic changes. *TNFAIP3* mutation or deletion is common in ocular adnexal EMZL and uncommon in EMZL in other sites,

while gains of 6p and loss of 6q are recurrently seen only in EMZL of the ocular adnexa.[1] Approximately one-quarter of ocular adnexal EMZL harbors t(14;18)(q32;q21)/*IGH*::*MALT1,* a translocation involving IGH and the *MALT1* gene; this translocation has also been found in EMZL arising in the liver, skin, and salivary glands, but is rare in EMZL in other sites.[83] Cases showing t(11;18)(q21;q21)/*BIRC3*::*MALT1* and t(3;14)(p14.1;q32)/*FOXP1*::*IGH* are also described.[70,84] In patients with bilateral ocular adnexal lymphoma, morphologic, immunophenotypic, and molecular genetic features are reported to be identical, consistent with a single neoplastic clone involving both sites, rather than two distinct, unrelated primary tumors.[72,73]

Staging, Treatment, and Outcome

Approximately 80% of patients have disease confined to the ocular adnexa, unilaterally or bilaterally.[71,77] In some studies, EMZLs are more likely to present with stage I disease than other types of lymphoma.[85] Localized low-grade lymphomas are usually treated with radiation. Intermediate or high-grade lymphoma, whether localized or widespread, are usually treated more aggressively.[65,70,79] Radiation therapy achieves excellent local control of disease; freedom from local recurrence is close to 100%.[85] Prevention and treatment of lymphoma away from the eye is not as successful, but the prognosis of ocular adnexal lymphoma is overall good. Overall survival (OS) at 5 years is approximately 90%, while the 5-year disease-free survival is approximately 70%.[77,85] When relapses occur, they involve lymph nodes, the opposite orbit, or other extranodal sites.[65,77]

Patients with disease localized to the ocular adnexa have a better prognosis than those with more widespread disease.[66,72,80,86] However, isolated bilateral ocular adnexal disease does not have a worse prognosis than unilateral disease.[77,87] In most reports, patients with high-grade lymphoma have had a worse outcome.[79,80,86,88,89]

Differential Diagnosis

Because most ocular adnexal lymphomas are low-grade lymphomas, the main differential diagnosis is with a reactive process, including inflammatory pseudotumor and reactive lymphoid hyperplasia. Inflammatory pseudotumor is a lesion with a variably cellular, polymorphous infiltrate of small lymphocytes, plasma cells, immunoblasts, and histiocytes, sometimes with eosinophils or neutrophils, in a stroma with areas that are hyalinized, edematous, or both. Immunohistochemical studies show a mixture of B cells, T cells, and polytypic plasma cells. In some instances, the plasma cells are predominantly IgG4 positive; these inflammatory pseudotumors are considered to represent IgG4-related sclerosing dacryoadenitis (if lacrimal gland is involved) and IgG4-related sclerosing orbital inflammation (if soft tissue is involved). Rare cases of lymphoma arising on a background of IgG4-positive inflammatory pseudotumor have been described.[90-92] Reactive lymphoid hyperplasia usually consists of follicular hyperplasia without a prominent diffuse lymphoid proliferation and without cytologic atypia. In favor of lymphoma is a dense, diffuse infiltrate composed predominantly of B cells. Such lesions usually express monotypic immunoglobulin and contain clonal B cells on molecular genetic analysis.

Lymphomas of Waldeyer's Ring

Waldeyer's ring is the circle of lymphoid tissue guarding the entrance to the alimentary and respiratory tracts. It consists of palatine tonsils, the nasopharynx, and the base of the tongue. Waldeyer's ring is the primary site for 5% to 10% of all non-Hodgkin lymphomas, accounting for more than half of all non-Hodgkin lymphomas primary in the head and neck.[93]

Clinical Features

Patients are mostly adults, and infrequently children, with a median age in the 50s, with a male-to-female ratio of 1:1 to 1:1.5.[93-96] A few patients are HIV positive or are iatrogenically immunosuppressed. Patients present with dysphagia, dyspnea, snoring, discomfort, foreign body sensation, or cervical lymphadenopathy. A minority have systemic symptoms.[96-98]

The tonsil is most frequently involved, accounting for more than half of Waldeyer's ring lymphomas, followed by the nasopharynx and the base of tongue.[93-95,99] Physical examination reveals a mass that is unilateral and exophytic in most cases, and may be smooth, polypoid, fungating, or ulcerated. The lymphoma is usually localized (stage I or II), but stage II disease (with cervical lymphadenopathy) is more common than stage I.[94,95]

Pathologic Features

Of cases, 60% to 84% are DLBCLs (**Fig. 59-3**). Other types are uncommon; they include FL, BL, mantle cell lymphoma (MCL), EMZL, and peripheral T-cell lymphoma.[93,94,98-100] MCL can present with involvement of Waldeyer's ring, but in contrast to

DLBCL, MCL is usually widespread at the time of diagnosis. Among children with Waldeyer's ring lymphoma, BL is much more frequent than among adults (**Fig. 59-4**).[96] The lymphomas have pathologic features overall similar to those seen in other sites. The DLBCLs include GCB and non-GCB subtypes, with a modest excess of non-GCB DLBCL. The majority are double-expressors (MYC positive, BCL2 positive).[101] A subset of the DLBCL and grade 3 FL have IRF4 rearrangement (see **Chapter 17**).[95,102,103]

Hodgkin lymphoma, almost always classic type, rarely presents with involvement of Waldeyer's ring. In most cases, Hodgkin lymphoma involves other sites as well. In one study, among cases confined to Waldeyer's ring, lymphocyte-rich classic Hodgkin lymphoma (CHL) was the most common type.[104]

Treatment and Outcome

Patients respond well to therapy, with a high proportion achieving complete remission. A better prognosis is associated with a tonsillar primary, favorable International Prognostic Index (IPI), localized disease,[93,94] therapy including rituximab and CNS-directed therapy,[101] and favorable ECOG score.[95]

Differential Diagnosis

Reactive lymphoid hyperplasia often causes enlargement of one or more of the components of Waldeyer's ring, sometimes mimicking a neoplasm. Preservation of reactive follicles and of crypts favors a reactive process. Infectious mononucleosis caused by primary EBV infection can mimic DLBCL or CHL, but some architectural preservation, polymorphous composition, positive in situ

hybridization for EBER, and clinical features, particularly age, can be helpful in differential diagnosis. Before making a diagnosis of DLBCL or CHL in Waldeyer's ring in a child or adolescent, evaluation for evidence of infectious mononucleosis is essential. Infiltration of crypt epithelium by lymphoid cells is normal and does not suggest EMZL. Atypical marginal zone hyperplasia with monotypic immunoglobulin light-chain expression in B cells that are polyclonal by molecular genetic analysis has been reported in Waldeyer's ring in rare children, and can mimic EMZL.[105] Nonkeratinizing nasopharyngeal squamous cell carcinoma, especially those cases with features of "lymphoepithelial carcinoma," and DLBCL may be difficult to distinguish on routine sections, but immunophenotyping readily establishes a diagnosis.

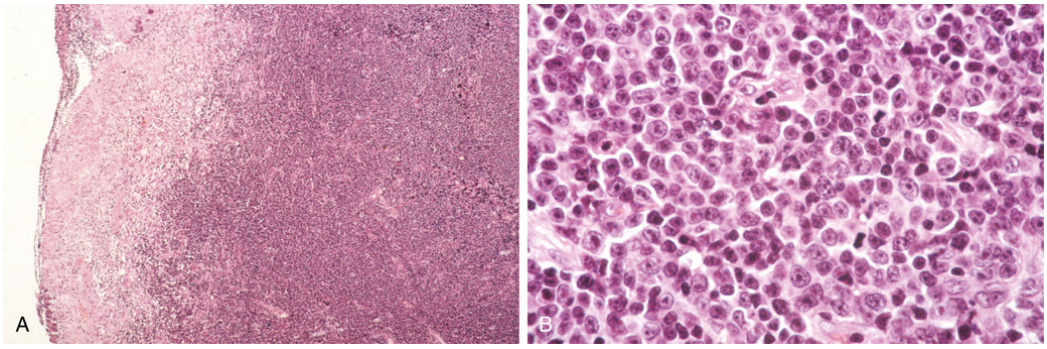

FIGURE 59-3 Diffuse large B-cell lymphoma, nasopharynx.A, The surface of the tissue is necrotic. The rest of the tissue is replaced by a dense lymphoid infiltrate. **B,** Higher power reveals a predominance of immunoblasts.

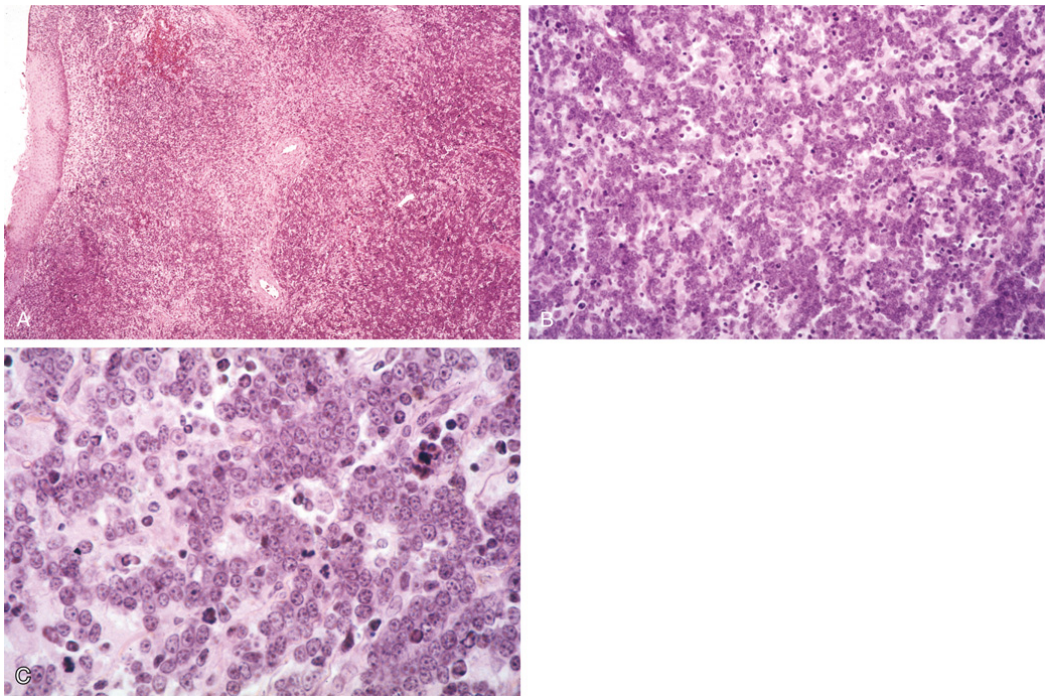

FIGURE 59-4 Burkitt lymphoma, tonsil of a child.A, A dense lymphoid infiltrate is seen beneath intact squamous epithelium. Normal crypt architecture has been obliterated. **B,** Medium power shows a striking starry-sky pattern. **C,** High power shows uniform medium-sized, round cells with finely stippled chromatin and small nucleoli with numerous mitotic figures and many admixed tingible body macrophages.

Lymphomas of The Nasal Cavity and Paranasal Sinuses

Among sinonasal malignancies, lymphoma is second in frequency only to squamous cell carcinoma.[106] Sinonasal lymphoma accounts for 0.2% to 2% of all lymphomas[107,108] and less than 5% of

extranodal lymphomas.[99] The incidence of lymphoma in this anatomic site is higher in Asia and South America.[109,110] Two main types of lymphoma occur: DLBCL and extranodal NK/T-cell lymphoma, nasal type (ICC)/extranodal NK/T-cell lymphoma (WHO 5th edition) (ENKTCL). Lymphomas that arise in paranasal sinuses are almost always DLBCL, and lymphomas arising in the nasal cavity may be ENKTCL or DLBCL.[110-113] ENKTCL is discussed in **Chapter 29**. Other types of sinonasal lymphoma are discussed below.

Clinical Features

Paranasal sinus lymphoma affects men more often than women (M:F = 1.5 to 2:1). It predominantly affects middle-aged to older adults,[107,108,111] and occasionally children.[114] A few patients have been HIV positive[111,115] or iatrogenically immunosuppressed.[111,116] Symptoms include nasal obstruction or discharge, facial swelling, pain or numbness, epistaxis, sinus pressure, toothache, or headache. The lymphoma may invade adjacent structures including orbit, base of skull, CNS, pterygopalatine fossa, nasopharynx, and palate.[107,114,115] Patients may present with neurologic abnormalities, proptosis, diplopia, decreased visual acuity, and even blindness.[108,109,111,114,115,117] Patients occasionally have fever and night sweats.[111,115] The maxillary sinus is the sinus most often involved, followed by the ethmoid, sphenoid, and frontal sinus. Frequently, multiple sinuses are involved concurrently.[107,108,111,114,115,118]

Pathologic Features

In Western countries, the most common lymphoma is DLBCL, followed by ENKTCL. Other types are infrequent or rare, but BL, FL,[109,114,115,117,118] EMZL,[107,111] high-grade B-cell lymphoma, not otherwise specified (NOS), high-grade B-cell lymphoma with concurrent MYC and BCL2 rearrangement, plasmablastic lymphoma,[107] peripheral T-cell lymphoma, NOS, and adult T-cell leukemia/lymphoma[111] presenting with sinus involvement have been described. Lymphomas in HIV-positive patients have been DLBCL and BL.[115] Those in children are most often BL, followed by DLBCL.[111,119] Immunophenotypic features are similar to those in other sites. DLBCL of non-GCB subtype is more common than GCB subtype.[101] The proportion of sinonasal B cell lymphomas containing EBV varies among series[110,117,120]; in a study from Massachusetts General Hospital, EBV was only encountered in DLBCL in patients with underlying immunodeficiency.[111]

Staging, Treatment, and Outcome

Most lymphomas are localized at presentation.[111] Patients with stage IV case disease may have involvement of CNS, lung, bones, kidney, or gastrointestinal (GI) tract.[114,115] Most DLBCL patients receive radiation and chemotherapy, sometimes with CNS prophylaxis. When the lymphomas relapse or progress, they frequently involve lymph nodes, and may also involve a variety of extranodal sites, including the CNS, lung, bone, ovary, testis, marrow, liver, spleen, and skin.[107,108,113,117] In one series, sinonasal DLBCL had a 5-year progression-free survival (PFS) of 50% and a 5-year OS of 56%[107]; use of rituximab was associated with better outcome.[107]

Differential Diagnosis

DBLCL and ENKTCL may be difficult to distinguish on routine sections. Angioinvasion and angiocentric localization, prominent necrosis, epitheliotropism, and pseudoepitheliomatous hyperplasia favor ENKTCL. DLBCL more commonly arise in paranasal sinuses, while nasal localization and midfacial destructive disease favor ENKTCL.[111,118,121] Most DLBCLs are composed of a diffuse proliferation of large cells, so any other cellular composition with a diffuse pattern, especially a mixture of small and large cells or of medium-sized cells, should raise the question of ENKTCL.[121] B-cell and NK/T-cell lymphomas can be distinguished easily with immunophenotyping. Absence of EBV excludes ENKTCL.

Salivary Gland Lymphomas

Clinical Features

Lymphoma accounts for 2% to 5% of salivary gland malignancies.[40,122] The lymphomas arise in the parotid in at least 70% of cases, in the submaxillary gland in 10% to 25% of cases, and in the sublingual and minor salivary glands in <10% of cases. Patients are affected over a broad age range, but the vast majority are over age 50, with a slight female preponderance. Patients present with an enlarging mass that is usually painless, but that may be accompanied by facial nerve paralysis or cervical lymphadenopathy.[40,122-126]

Pathologic Features

EMZL of mucosa-associated lymphoid tissue (see **Chapter 18**) and DLBCL account for nearly all salivary gland lymphomas. EMZL is the most common lymphoma arising in salivary gland parenchyma. Of

salivary gland EMZLs, 30% to 35% occur in patients with autoimmune disease, mainly Sjögren syndrome, and rarely, rheumatoid arthritis.[125,126] Salivary gland lymphomas in Sjögren syndrome patients are almost always EMZL.[126] EMZL predominantly affect females, in part because of the high ratio of women to men with Sjögren syndrome. EMZL usually arises in a background of lymphoepithelial sialadenitis (LESA) showing large, well-formed lymphoepithelial lesions (LELs). In contrast to LESA without lymphoma, LELs in EMZL are surrounded by large haloes and broad intersecting strands and sheets of monocytoid B cells, distorting and obliterating the salivary gland parenchyma. Also present are scattered reactive follicles and plasma cells, sometimes in large aggregates. In salivary glands other than the parotid, LELs may be less conspicuous, but histologic features are otherwise similar.

Salivary gland EMZL commonly harbor trisomy 3, which is especially frequent in patients without Sjögren syndrome.[125] A small minority have trisomy 18 or a rearrangement of *MALT1*. Most salivary gland EMZL express IgM with strong rheumatoid factor activity, so that IgG, likely in immune complexes in inflamed tissues, serves as the autoantigen that contributes to the chronic antigenic stimulation thought to drive the pathogenesis of some EMZL, including those arising in salivary glands.[127] Recurrent activating mutations in certain G-protein coupled receptors occur in EMZL; mutated *GPR34* and rarely t(X;14)(p11;q32)/*IGH*::*GPR34* appear specific for salivary gland EMZL.[128,129] Maintenance of GPR34 signaling in EMZL may be related to ligands produced by salivary gland LELs.[130] These changes may promote emergence and expansion of B-cell clones, particularly around LELs.

FL may also arise in the area of salivary glands but usually involves lymph nodes in the vicinity rather than salivary gland parenchyma. Pathologic features are similar to those of other nodal FLs (see **Chapter 17**). Salivary-gland DLBCL affects men and women equally[124] and has features similar to those of DLBCL in other sites (see **Chapter 22**). Some of the DLBCL may represent large-cell transformation of an underlying EMZL or FL.[40,122,123] Rare cases of BL,[122] peripheral T-cell lymphoma, NOS, anaplastic large cell lymphoma, and ENKTCL have been reported.[131]

Staging, Treatment, and Outcome

The majority of patients with salivary gland lymphoma, both EMZL and DLBCL, present with unilateral, localized disease.[124,125] EMZL occasionally spreads to lymph nodes or other MALT sites, but in general, prognosis is very favorable, with 5-year OS of >90%.[125] In a minority of cases, EMZL undergoes large cell transformation to DLBCL.[40,122,123] Improvements in therapy have improved the prognosis of salivary gland DLBCL; 5-year disease-specific survival among recently treated patients was 84%.[124]

Differential Diagnosis

In the differential diagnosis of EMZL and LESA, more extensive monocytoid B-cell proliferation outside LELs and more extensive glandular obliteration favor lymphoma. Monocytoid B cells confined to LELs and even discrete haloes around LELs can be seen in LESA, but broad intersecting bands of monocytoid B cells support a diagnosis of lymphoma. Demonstration of monotypic immunoglobulin in lymphoid cells or plasma cells supports

lymphoma. Molecular genetic studies are not usually helpful because B-cell clones are reported in more than 50% of cases of LESA.[132] HIV-associated cystic lymphoid hyperplasia involves lymph nodes, is often bilateral, and typically consists of multiple dilated ducts surrounded by floridly hyperplastic follicles with attenuated mantles. LELs are not conspicuous, although large numbers of lymphoid cells may be found within the epithelium of dilated ducts. The differential diagnosis may also include IgG4-related sialadenitis, which typically involves submandibular glands.[133] These patients may have dry mouth and may carry a clinical diagnosis of Sjögren syndrome. IgG4-related sialadenitis may have prominent follicular hyperplasia and a dense lymphoid infiltrate with numerous plasma cells, but LELs are inconspicuous, and there is typically bandlike and storiform sclerosis.

Lymphomas of The Oral Cavity

Clinical Features

Approximately 2% of all extranodal lymphomas arise in the oral cavity (i.e., palate, gingiva, tongue, buccal mucosa, floor of mouth, and lips).[68,134] Lymphoma arising in the bones of the jaw may present in the oral cavity.[135] Most patients are immunocompetent, middle-aged to older adults, with median age in the 6th or 7th decade and slight male preponderance.[134-138] Patients with HIV infection have a tendency to develop oral lymphomas.[137-139] HIV-infected patients are almost all males with an approximate median age of 40 years.[137,139,140] Oral lymphoma has also been reported rarely in transplant recipients.[138]

Patients present with soft tissue swelling, pain, mucosal ulceration or discoloration, paresthesias, anesthesia, or loosening of teeth.[135,138,139,141,142] The sites most often affected, in both HIV-positive and HIV-negative patients, are the palate/maxilla and gingiva, with tongue, buccal mucosa, floor of mouth, and lips affected less often.[134,135,137,139,140] Physical examination reveals an exophytic, often polypoid mass in the majority of cases. In a minority, the lymphoma is an infiltrative, ulcerated lesion with raised margins.[134]

Pathologic Features

A wide variety of lymphomas arise in the oral cavity, although nearly all are non-Hodgkin lymphoma.[143] Among immunocompetent patients, approximately half are DLBCL. Next most common is FL (**Fig. 59-5**), followed by EMZL, peripheral T-cell lymphoma, NOS, extranodal NK/T-cell lymphoma, BL, and others.[135-137] EMZL may arise in minor salivary glands. A predilection for FL to involve the palate is reported.[138] Mycosis fungoides occasionally involves the oral cavity. The majority of these cases are found in the setting of long-standing, advanced disease, but in exceptional cases, the first manifestation of mycosis fungoides is in the oral cavity. Aggressive epidermotropic CD8-positive cutaneous T-cell lymphoma may also involve the oral cavity.[144,145]

Oral lymphomas in HIV-infected individuals are less heterogeneous than those in immunocompetent patients; they are almost all diffuse high-grade lymphomas. Most are DLBCL, with rare BL.[40,137-140] Plasmablastic lymphoma is a distinctive type of DLBCL often arising in immunosuppressed individuals that typically occurs

in the oral cavity and other extranodal sites; it is composed of cells with the appearance of immunoblasts or plasmablasts, with vesicular nuclei, prominent nucleoli, and scant to moderately abundant eccentrically placed cytoplasm with a paranuclear hof, high mitotic rate, frequent single cell necrosis, and scattered tingible-body macrophages. The immunophenotype is distinctive: neoplastic cells typically lack CD20 and have a plasma cell immunophenotype: CD138 positive, IRF4/MUM1 positive, CD79a variable, often with monotypic cytoplasmic immunoglobulin.[140,146]

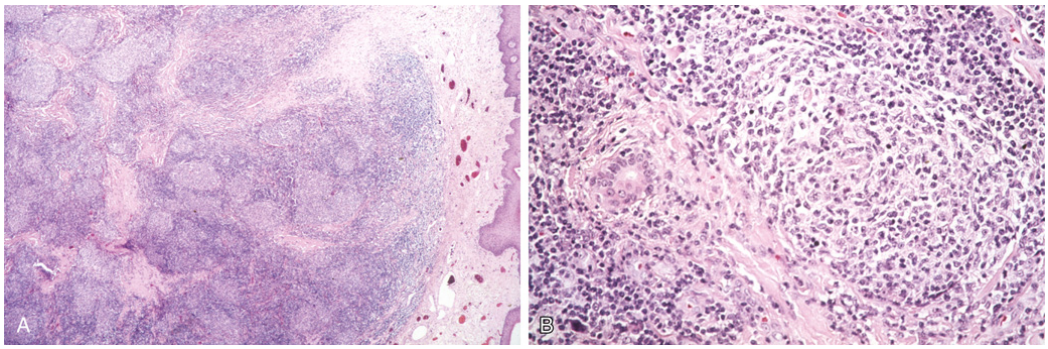

FIGURE 59-5 Follicular lymphoma, oral cavity. This lymphoma was a relapse from an orbital primary. **A,** Low power shows crowded follicles within soft tissue beneath squamous epithelium. **B,** Poorly circumscribed, neoplastic follicles predominantly contain centrocytes and are seen adjacent to small acini of minor salivary gland.

Most HIV-associated oral lymphomas, including plasmablastic lymphoma, contain EBV.[137-140] In contrast, only about 9% of oral

lymphomas in nonimmunosuppressed patients are EBV positive.[137,138]

Staging, Treatment, and Outcome

Disease is localized in approximately 70% of cases.[135,140] The proportion with localized and disseminated disease is similar in HIV-positive and HIV-negative patients. Outcome depends on stage, type of lymphoma, type of treatment and HIV status, so that patients with localized, histologically low-grade lymphomas have an excellent outcome, while patients with high-grade lymphoma or disseminated disease have worse survival.[40,135,141,143] Improvements in therapy in recent years have been associated with improved outcome.[143]

Differential Diagnosis

Oral lymphoma can mimic dental conditions such as periodontal disease, acute necrotizing gingivitis, and dental infections.[139,142] Some lesions resemble carcinoma.[135] In HIV-positive patients, Kaposi sarcoma and deep fungal infections also enter the clinical differential diagnosis.[139]

Thyroid Lymphomas

Clinical Features

Primary lymphoma of the thyroid is uncommon. It accounts for 1% to 5% of all thyroidal malignancies and for 1% to 2.5% of all lymphomas.[147] Patients are affected over a wide age range, but most are older adults with a median age between 60 and 70 years. There is a female preponderance (3:1 to 4:1).[147-152] Most patients have Hashimoto thyroiditis. Patients with Hashimoto thyroiditis have an

estimated 40-fold to 80-fold increased risk for lymphoma.[148,151] Patients complain of the presence of a mass, which may be rapidly enlarging. They may also have dysphagia, cough, dyspnea, and hoarseness, sometimes with tracheal compression.[147,151,152] A minority of patients with DLBCL have systemic symptoms.[153]

Pathologic Features

On gross examination, tumors range from 0.5 to 19 cm (mean, 4–7 cm) and form multinodular or diffuse, firm, or soft masses with smooth, pale tan or white-gray surfaces on sectioning.[151,153] DLBCL is the most common type, making up 50% to more than 90% of cases. DLBCL is bilateral in about 25% of cases, and it commonly involves adjacent soft tissue and other structures.[153] EMZL is next most common, accounting for 10% to 28% of cases. Lymphoma is bilateral in one-third of cases.[148] In a subset of the DLBCL there is a component of EMZL, consistent with transformation of the underlying low-grade lymphoma.[147,149,151,152,154] Of note, in some Asian series, EMZL is more common than DLBCL.[155,156] FL accounts for 2% to 10% of cases.[149,150,155,156] All other types of lymphoma are quite uncommon; among those reported are BL,[157] peripheral T-cell lymphomas, and Hodgkin lymphomas.[147,150,152,156] Most of the Hodgkin lymphomas are nodular sclerosis CHL.[158,159]

The histologic and immunophenotypic features are similar to those seen in other sites. DLBCL expresses pan–B-cell markers and includes GCB and non-GCB subtypes.[153,154] In one study, 29% were double-expressors (MYC positive, BCL2 positive).[153] Thyroidal EMZL has some distinctive characteristics, often containing a characteristic type of lymphoepithelial lesion showing round

aggregates of marginal zone cells filling and expanding the lumens of thyroid follicles, so-called “MALT-ball” LELs.[151] Follicular colonization tends to be prominent, in some cases resulting in a follicular architecture so striking that it mimics FL. Blast transformation of neoplastic cells within colonized follicles is more common in the thyroid than elsewhere.[160] Changes of Hashimoto thyroiditis are often seen adjacent to the lymphoma (**Fig. 59-6**).[151] Approximately 50% of thyroid EMZL have a *FOXP1*::*IGH* translocation [(3;14)(p14.1;q32)] that results in upregulation of FOXP1, and that could play a role in the pathogenesis of EMZL.[84,154] This translocation is also found in a subset of thyroid DLBCL, all of non-GCB type, suggesting large cell transformation of an underlying EMZL. *FOXP1*::*IGH* is not found in FL or Hashimoto thyroiditis.[154] The majority of thyroid EMZL have pathogenic mutations of *TET2, CD274* (PD-L1), or *TNFRSF14*; many have mutated *TNFAIP3* and deletion of *CD274*.[128] The changes may deregulate interactions of neoplastic B cells with T cells, contributing to lymphomagenesis.

Although FL of the thyroid is uncommon, it has characteristic features. Immunostaining for BCL2 helps divide thyroid FL into two types: (1) $BCL2^+$ FL, which is usually $CD10^+$, $BCL6^+$, low-grade, positive for *BCL2* translocation, often with widespread disease; and (2) $BCL2^-$ FL, which is usually $CD10^-$ or $weak^+$, $BCL6^+$, grade 3 or occasionally grade 2, lacks *BCL2* translocation, usually with disease confined to the thyroid.[161,162] FLs that are $BCL2^-$ and lack *IGH*::*BCL2* typically lack mutations of epigenetic modifiers such as *EZH2, KMT2D, ARID1A,* and others that are common in $BCL2^+$ FLs with *IGH*::*BCL2*.[161]

Staging, Treatment, and Outcome

Most patients have localized disease at presentation; 50% to 70% of patients have stage I disease. Most of the remainder have stage II disease, usually with cervical or perithyroidal lymphadenopathy. A minority has more widespread nodal and extranodal involvement. Extranodal sites that may be involved include bone marrow, GI tract, lungs, liver, and bladder.[151,152] EMZL are almost always localized (stage I or II). Stage III and IV lymphomas are usually DLBCL.[147,151]

Patients are usually treated with radiation, chemotherapy, or both.[147,151] Median OS of DLBCL is 11 to 13 years, with a 5-year OS of 73% to 76%,[149,153] while EMZL has a 5-year OS of 94% and a median OS of 16 to 17 years, with only 1% to 4% dying of lymphoma.[148-150] Survival of DLBCL patients is better with combined radiation and chemotherapy, including rituximab.[153] Patients with EMZL often do well when treated with radiation alone.[149]

Differential Diagnosis

Both Hashimoto thyroiditis and EMZL have reactive lymphoid follicles and LELs, but in favor of EMZL are obliteration of thyroid parenchyma by a diffuse infiltrate of marginal zone B cells and lymphoid or plasma cells expressing monotypic immunoglobulin. LELs are larger and more numerous in EMZL. Cases of extramedullary plasmacytoma arising in the thyroid have been described; some of these may represent EMZL with marked plasmacytic differentiation. Reactive follicles, an extrafollicular component of B cells, particularly with the morphology of marginal zone cells, and LELs make plasmacytoma unlikely. It may be difficult to distinguish undifferentiated carcinoma from DLBCL on routine

sections, but diagnosis can be established using immunohistochemical studies.

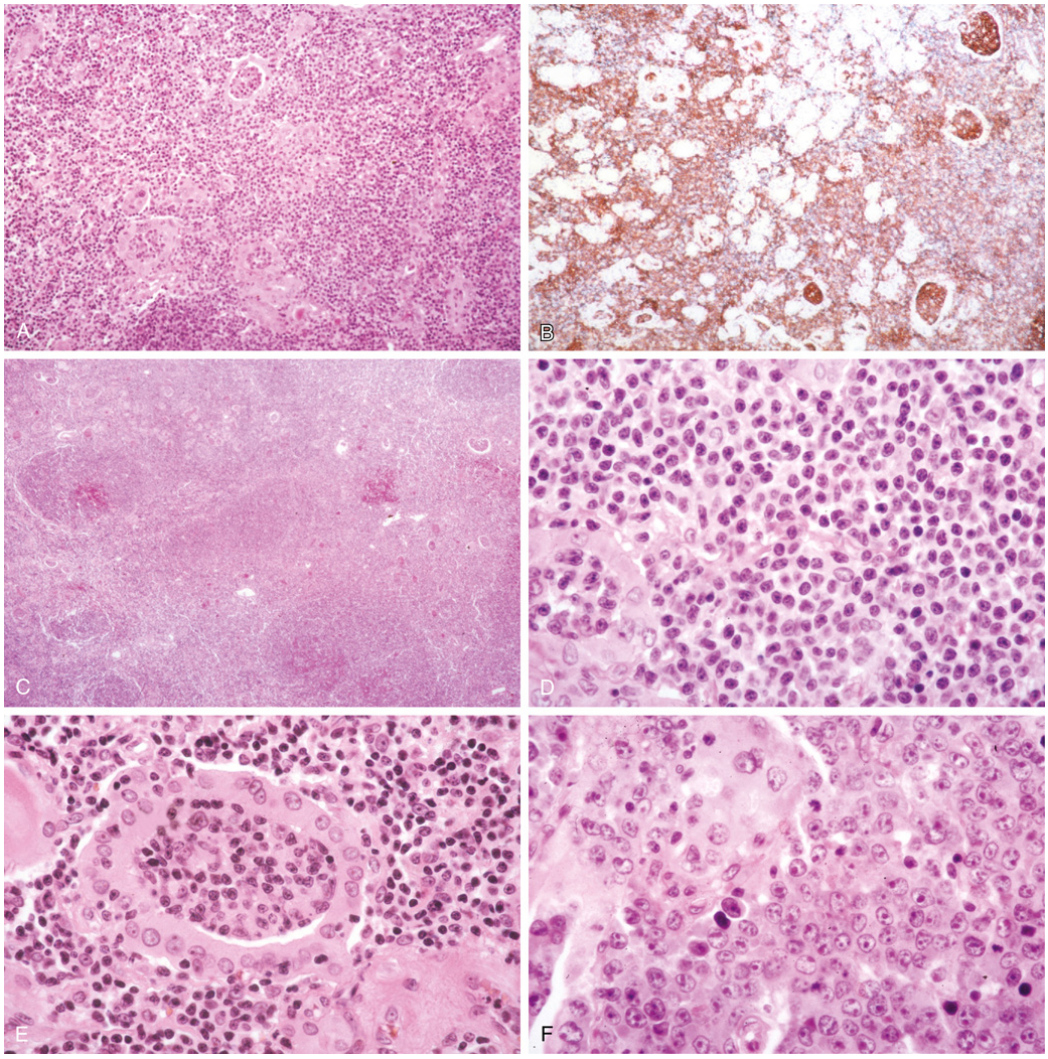

FIGURE 59-6 Thyroid gland with extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue **(A–E)** with large cell transformation **(F)**. Other areas showed Hashimoto thyroiditis. **A,** Low power shows obliteration of the normal parenchyma. **B,** A stain for CD20 highlights the diffuse infiltrate of B cells; several rounded lymphoepithelial lesions are seen (immunoperoxidase technique on paraffin section). **C,** In areas there is vague

nodularity, consistent with colonization of reactive lymphoid follicles by neoplastic marginal zone cells. **D,** The marginal zone cells are small, with oval-to-slightly-irregular nuclei and moderate amount of pale cytoplasm. **E,** MALT-ball lymphoepithelial lesion. The epithelium of the thyroid follicle shows oxyphil change. **F,** An area of large cell transformation. Many of the neoplastic cells are immunoblasts.

Laryngeal Lymphomas

Clinical Features

Primary laryngeal lymphoma is rare, accounting for fewer than 1% of laryngeal malignancies.[163,164] Patients are mostly middle-aged to older adults with few young adults and children affected. There is a slight male preponderance.[40,164-167] Several patients have had concurrent laryngeal squamous cell carcinoma or other malignancies.[166,167] Rarely, patients are HIV positive[40,165] or have another underlying immunodeficiency.[168]

Patients present with hoarseness, dyspnea, progressive or acute laryngeal obstruction, sore throat, foreign body sensation, or dysphagia.[40,164,166,167] The tumors are usually smooth-surfaced, submucosal, raised, often polypoid lesions.[165,166,169] Pedunculated tumors may prolapse into the airway.[165,167] Laryngeal lymphomas may arise from the lymphoid tissue that can be found in the larynx, mainly in the epiglottis and supraglottic larynx, correlating with the distribution of lymphomas.[169]

Pathologic Features

DLBCL and EMZL, together, account for approximately 80% of cases. Their pathologic features are similar to those in other sites.[164,166,167,169,170] Rare cases of FL[164] and peripheral T-cell lymphoma[166,171] are reported. Extranodal NK/T-cell lymphoma (see **Chapter 29**) is rare but is reported.[163,165,171] It is more common in Asians and Native Americans and accounts for about 2% of all extranodal NK/T-cell lymphomas.[163]

Staging, Treatment, and Outcome

In approximately 75% of cases, patients have Ann Arbor stage I disease; most of the remainder have stage II disease.[40,164-167] In a few EMZL, the larynx has been involved simultaneous with involvement of other extranodal sites in the head and neck.[40,172] Most patients with EMZL and DLBCL can be successfully treated with a combination of surgery and radiation or chemotherapy,[40,173] although laryngeal lymphoma rarely results in sudden death caused by acute airway obstruction.[169] When EMZL patients develop relapses, they tend to be isolated, extranodal tumors in the upper respiratory tract, stomach, orbit, and skin; when relapses occur, there may be long disease-free intervals, similar to EMZL in other sites.[40,166]

Pulmonary Lymphomas

Primary pulmonary lymphoma is defined traditionally as lymphoma presenting as pulmonary lesion(s), with no clinical, pathologic, or radiographic evidence of lymphoma elsewhere in the past, at present, or for 3 months after presentation,[174,175] but others accept cases in

which staging reveals disease outside the lung if pulmonary disease predominates.[176]

Clinical Features

Primary pulmonary lymphomas account for 0.3% of primary lung neoplasms,[175] <1% of all lymphomas,[177,178] and 3.6% of extranodal lymphomas.[175] Patients are typically adults (median age, about 60 years). It is uncommon before age 30,[174,176-180] although rare cases in younger patients are reported.[181,182] Most studies show a slight male predominance.[176-178]

Approximately 70% of cases are EMZL.[174,176,177,182] Pulmonary EMZL affects females more often in some reports[183] and affects males and females roughly equally in others[184,185] over a broad age range, with a median age in the 6th decade.[184,185] Many pulmonary lymphoma patients are asymptomatic at presentation. The remainder have pulmonary (cough, dyspnea, hemoptysis, or chest pain) or constitutional symptoms. Asymptomatic patients usually have EMZL.[174,176,179,180,182,186,187] Approximately one-third of patients have an associated autoimmune disease,[180,183] the most frequent of which is Sjögren syndrome.[176,177,180] Monoclonal paraproteins are relatively common,[174,176,183] being found in 10%[184] to 43% of cases.[180]

A small number of patients are HIV positive.[188] Lung allograft recipients may develop posttransplantation lymphoproliferative disorders (PTLD) involving the lung.[177]

Radiologic Features/Patterns of Involvement

Patients have single or multiple unilateral or bilateral lesions that can be nodules, masses, or infiltrates that may resemble consolidated lung.[174,176,177,179,180,186,187] Pulmonary EMZL involves the lungs unilaterally in 70% to 75% of cases, as single or multiple lesions.[183,184] Pulmonary lymphomas rarely show endobronchial or diffuse submucosal involvement.[177] Fewer than 10% are associated with a pleural effusion.[174,176]

Pathologic Features

Pulmonary EMZL has features similar to those of EMZL in other anatomic sites. Lymphoma spreads in a diffuse and interstitial pattern. Most cases have interspersed reactive lymphoid follicles and LELs formed with bronchial or bronchiolar epithelium (**Fig. 59-7**). Infiltration of the pleura is frequent.[176,180,189] Occasional cases are associated with amyloid deposition[179,180,184,189]; this seems to be more frequent in the lung than in other sites. A variety of genetic alterations are described. Among the most important is t(11;18)(q21;q21), a translocation almost exclusively found in EMZL, resulting in *BIRC3*::*MALT1* gene fusion, occurring in 30% to 50% of pulmonary EMZL.[83,183,190]

DLBCL is the next most common type of primary pulmonary lymphoma, accounting for approximately 20% of cases. Many have a component of EMZL, consistent with large-cell transformation of the EMZL.[174,176,180,182,183,187] Other types of lymphoma are uncommon; they include FL,[176,179,182] BL,[176] lymphomatoid granulomatosis (see **Chapter 28**),[182] peripheral T-cell lymphoma, NOS,[176,182] anaplastic large cell lymphoma,[175] and rarely, CHL.[177]

Nearly all HIV-associated cases are diffuse, high-grade, EBV-positive B-cell lymphomas.[188,191]

Staging, Treatment, and Outcome

Lymphoma may be confined to the lungs, or may involve lymph nodes or other extranodal sites, especially so-called "MALT sites."[178,186] EMZL is stage I or II in about two-thirds of cases.[184] Patients with EMZL may develop relapses in the lung and other MALT sites, especially stomach and salivary glands, as well as lymph nodes, and some undergo transformation to DLBCL. Overall, patients do well, and survival is good with a variety of therapeutic approaches.[174,176,177,180,182,186,189] In one series of pulmonary EMZL, 15-year disease-specific survival was 95%, median PFS was 7.5 years and median OS was 15.7 years,[184] while in another, 5-year OS was 87% and 5-year PFS was 75%.[185] Inferior PFS has been associated with stage III or IV disease, MALT IPI of 2 or 3, involvement of MALT sites in addition to lung, and multifocal lung disease.[184] OS is inferior with older patient age.[185]

Pulmonary DLBCL have a prognosis similar to[180,182] or worse than[174,176] pulmonary EMZL. DLBCL patients usually receive more aggressive therapy; this could account for the lack of difference in outcome some have observed.

Differential Diagnosis

The main problem in differential diagnosis is distinguishing EMZL from chronic inflammatory processes with lymphoid hyperplasia, including nodular lymphoid hyperplasia, lymphocytic interstitial pneumonia, and IgG4-related disease.[183] In favor of lymphoma is a

predominance of B cells with the morphology of marginal zone cells in a diffuse pattern outside follicles, CD43 co-expression by the B cells, monotypic immunoglobulin expression by lymphocytes or plasma cells, and clonal immunoglobulin gene rearrangement. In favor of a reactive process is a mixture of B and T cells, with B cells mostly confined to follicles. LELs are frequent in lymphoid hyperplasia, but they are less frequent than in EMZL, and the intraepithelial lymphocytes can be B or T cells, in contrast to the predominance of B cells seen in EMZL.[179]

Lymphomas of The Pleura and Pleural Cavity

Lymphomas rarely arise primarily in the pleural cavity and other body cavities. Several distinctive types have been described: *primary effusion lymphoma* (see **Chapter 28**), an aggressive HHV8-positive lymphoma mainly affecting HIV-positive individuals, *pyothorax-associated lymphoma* (see **Chapter 28**), a distinctive type of DLBCL with chronic inflammation, and HHV-8 and EBV-negative primary effusion-based lymphoma (ICC)/*fluid overload-associated large B-cell lymphoma* (WHO 5th edition), which presents as serous effusions, typically in older adults with cardiovascular, renal, or hepatic disease resulting in fluid overload.[192,193] Fluid overload-associated large B-cell lymphoma has been referred to by a variety of names, including PEL-like lymphoma and HHV8-unrelated PEL-like lymphoma. By definition, they are negative for HHV8. In contrast to PEL, the majority are CD20 positive, a minority are EBV positive, and the prognosis is significantly more favorable.[1]

Lymphomas of The Thymus

Several types of lymphoma can arise in the anterior mediastinum, including the thymus: primary mediastinal large B-cell lymphoma (see **Chapter 22**), CHL and mediastinal gray zone lymphoma (**Chapter 27**), T-lymphoblastic leukemia/lymphoma (see **Chapter 41**), and EMZL of mucosa-associated lymphoid tissue (see **Chapter 18**). Thymic EMZLs are rare; they are distinctive in that they form LELs with Hassall corpuscles and usually express IgA (**Fig. 59-8**).[194]

Cardiac Lymphomas

Clinical Features

Primary cardiac lymphoma predominantly or exclusively involves the heart.[195,196] Primary cardiac lymphoma is rare; secondary cardiac involvement by lymphoma arising elsewhere is much more common[197] and is frequent among patients dying of lymphoma.[198] Primary cardiac tumors are uncommon; lymphoma accounts for 1% to 2% of primary cardiac neoplasms.[196,199,200] Primary cardiac lymphomas occur over a broad age range, but mainly occur in older adults (median, 7th decade), with males more affected than females.[195,198-205] They also occur in immunocompromised HIV-positive patients and allograft recipients (Figs. **59-9**–**59-10**).[201,206] Those arising in HIV-positive individuals affect younger individuals with a pronounced male preponderance.[201] Children rarely develop cardiac lymphoma.[207,208] Patients present with chest pain, dyspnea, congestive heart failure, fatigue, syncope, or arrhythmias.[195,198,200,201] Pericardial effusion, sometimes with

tamponade, and pleural effusion are common.[198,200,209] Complete atrioventricular block has been described.[209]

Primary cardiac lymphoma most often involves myocardium.[196] Valvular involvement is rare, but is described.[196,198] The lymphomas involve the right side of the heart more often than the left side.[197,198] Diagnosis may be based on biopsy or pericardial fluid cytology.[200,201,203,210,211] The prognosis has been poor, because diagnosis was often delayed and only made postmortem, and because fatal arrhythmias often accompanied chemotherapy.[195] Among more recent cases, prognosis appears better with earlier diagnosis and improvements in imaging and therapy, including careful monitoring of cardiac function. Optimally treated patients may attain a sustained complete remission.[196,199,200,212] Prognosis is worse with older age and advanced stage disease.[200,204,205]

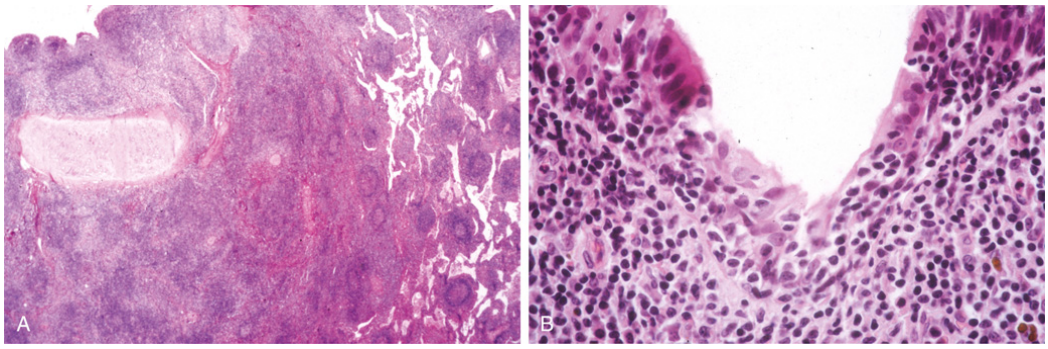

FIGURE 59-7 Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, lung.A, A dense diffuse lymphoid infiltrate extends from the bronchial lumen *(upper left)*, past bronchial cartilage and into surrounding lung. At the periphery, there is an interstitial pattern. Reactive follicles are scattered evenly throughout the lymphoid infiltrate. **B,** Higher power shows bronchial epithelium with lymphoepithelial lesions; lymphoid cells are small with pale cytoplasm.

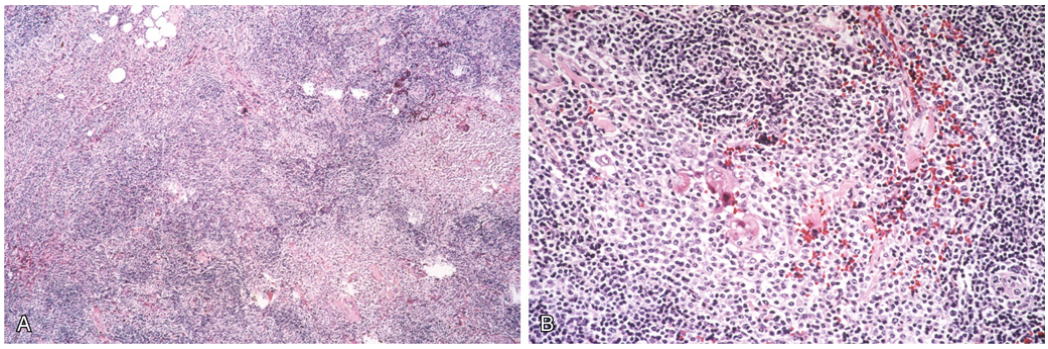

FIGURE 59-8 Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, thymus.A, The normal thymic tissue is obliterated by a mottled pale and dark lymphoid infiltrate. **B,** Pale areas correspond to aggregates of marginal zone cells, shown here surrounding and invading a Hassall corpuscle.

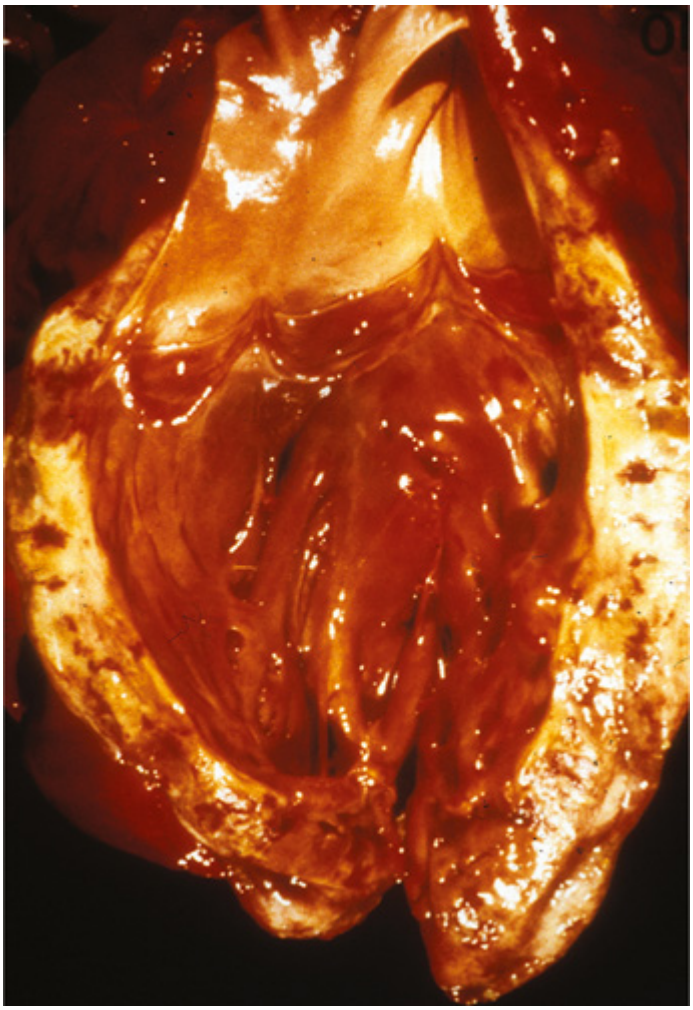

FIGURE 59-9 Cardiac lymphoma in a renal transplant recipient. Yellow tumor can be seen on cross-section, replacing normal myocardium.

Pathologic Features

Primary cardiac lymphomas are nearly exclusively (DLBCL) (**Fig. 59-10**).[195,201,209,211,212] Non-GCB immunophenotype is slightly more common than GCB type.[198] In one study, 53% of DLBCLs were double-expressors, co-expressing MYC and BCL2.[200] Fibrin-associated DLBCL, often mimicking atrial myxoma, represents a

subset of cases.[198,200] Rare cases of peripheral T-cell lymphoma, B and T lymphoblastic lymphoma, and BL are reported.[198,200,207,208] Primary cardiac extracavitary primary effusion lymphoma (HHV8 positive) has been reported in an HIV-positive male.[213] One double-hit high-grade B-cell lymphoma is reported.[198] Secondary cardiac lymphomas are pathologically much more heterogeneous.[197]

Differential Diagnosis

Because cardiac lymphomas are rare, lymphoma is rarely suspected prior to biopsy. Cardiac lymphoma can mimic much more common, non-neoplastic causes of cardiac dysfunction. The combination of right-sided tumor and high LDH, particularly in an immunocompromised patient, is suspicious for lymphoma.

Lymphomas of The Breast

Clinical Features

Primary lymphoma of the breast is usually defined as lymphoma confined to one or both breasts, with or without ipsilateral axillary lymph node involvement, but without disease elsewhere at presentation, in a patient without a history of lymphoma.[214] The breast is among the least-common primary sites for lymphoma, possibly correlating with sparse endogenous mammary lymphoid tissue. Only approximately 0.5% of primary breast malignancies are lymphomas.[214] Less than 1% of lymphomas arise in the breast.[215] Most patients are middle-aged to elderly women, although occasionally young adult or adolescent females and rare males are affected.[214-219] Occasionally lymphomas arise in pregnant or lactating women.[214,220] Patients often present with a palpable breast

mass.[221] Occasional lymphomas are detected by mammography.[218,222,223] Constitutional symptoms are uncommon.[216] In 0% to 25% of cases in different series, patients present with bilateral disease.[214,216,219,224] Patients usually have discrete, mobile mass(es), without fixation to either superficial or deep structures. Involvement of the overlying skin is described[225]; the appearance can mimic inflammatory carcinoma.[226] Ipsilateral axillary lymphadenopathy involvement varies widely among series, from 11%[218] to ~50%.[216]

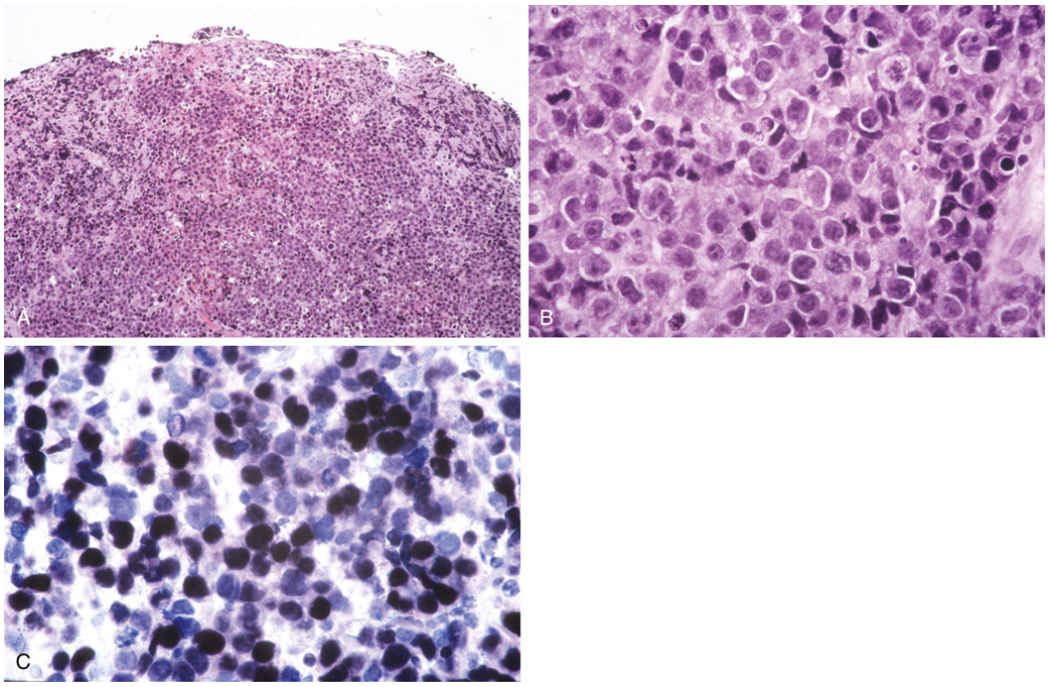

FIGURE 59-10 Cardiac diffuse large B-cell lymphoma in a HIV-positive male.A, A dense lymphoid infiltrate forms a mass involving the right side of the heart. **B,** Higher power shows large atypical lymphoid cells with frequent mitoses. **C,** Neoplastic cells contain Epstein-Barr virus (in situ hybridization on a paraffin section using a probe for EBER).

Breast implant-associated anaplastic large cell lymphoma (BI-ALCL) is a rare, distinctive, CD30-positive, ALK-negative T-cell neoplasm arising in association with breast implants (see **Chapter 36**).[227-229] Rare cases of fibrin-associated large B-cell lymphoma and DLBCL with chronic inflammation have also been reported in association with breast implants.[230,231]

Pathologic Features

The tumors vary greatly in size, from approximately 1 to 12 cm.[219] They are usually discrete but nonencapsulated, with a fleshy or soft consistency and white-gray or white-pink color. In some cases, there is more than one discrete mass.[214,218,226] Nearly all primary breast lymphomas are B-lineage (BI-ALCL being an exception). In most series, DLBCL is the most common type, comprising ~70% of cases (**Fig. 59-11**). [217,221,222,232] DLBCL of GCB is less common than DLBCL of non-GCB ABC type.[215,224] The DLBCLs are typically EBV negative.[233] Primary breast DLBCL of non-GCB type often have mutations of *MYD88* (MYD88 L265) and *CD79B,* resulting in activation of the NFκB pathway, contributing to lymphomagenesis.[234] Translocations of *BCL2, BCL6,* and *MYC* are absent or rare.[234]

Most of the remainder are either EMZL of mucosa-associated lymphoid tissue (**Fig. 59-12**) or FL. T-cell lymphomas are rare,[223,226] and are not well characterized except for BI-ALCL (see **Chapter 36**). Other lymphomas rarely arising in the breast include B-lymphoblastic lymphoma and CHL.[215,221]

DLBCL affects women over a wide age range. FL and EMZL affect middle-aged and older women. BL is mainly found in young women who may be pregnant or postpartum; a minority of DLBCL are also found in this clinical setting.[214,218,220,226,232,235] BL is more often synchronously bilateral than other breast lymphomas. Among African patients, a higher proportion of breast lymphomas are BL than in other geographic areas.[236]

Although breast lymphomas appear circumscribed grossly, they often show invasion into surrounding tissues at the periphery of the mass.[218] The neoplastic cells infiltrate around and within mammary

ducts and lobules, sometimes with obliteration of these structures. FL of all grades (1–3) have been reported. EMZLs have an appearance similar to other sites, except that LELs are not usually found.[218,223,226]

Treatment and Outcome

The outcome of patients with lymphomas of the breast has improved over time. DLBCL of the breast is relatively aggressive. It can recur in the same breast or spread to lymph nodes and various extranodal sites including CNS, contralateral breast, liver, spleen, and others.[214,217,219,224,232] EMZL patients typically remain well after treatment or develop relapses that are usually extranodal (subcutis, larynx, chest wall, parotid, orbit), but occasionally involving lymph nodes, although usually without generalized disease. Large cell transformation has been reported. Thus, mammary EMZL behaves in a manner similar to EMZL in other sites.[218,220,232] FL patients may develop generalized disease, similar to nodal FL.[218] With appropriate therapy, BL patients may attain long-term survival.[219]

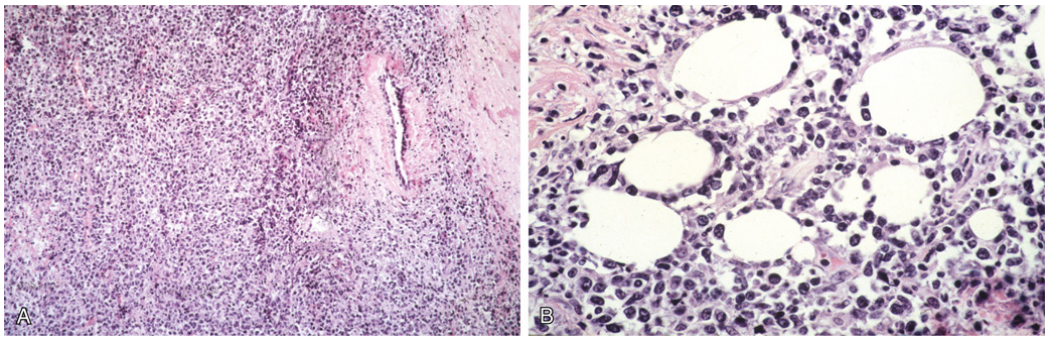

FIGURE 59-11 Diffuse large B-cell lymphoma, breast.A, Low power shows a dense, diffuse lymphoid infiltrate surrounding a ductule and replacing normal tissue. **B,** Large atypical lymphoid cells with irregular nuclei infiltrate fat.

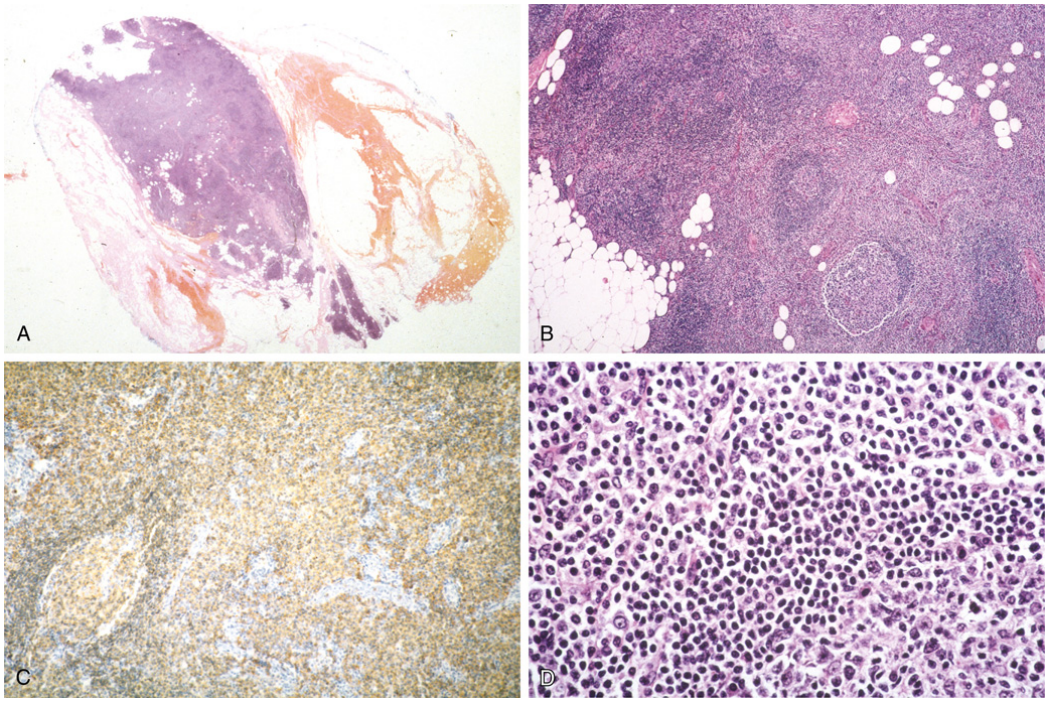

FIGURE 59-12 Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, breast.A, Whole mount of the excisional biopsy specimen shows a well-delineated nodule of lymphoid tissue. **B,** Medium power shows a diffuse lymphoid infiltrate with scattered reactive follicles. **C,** A stain for CD20 shows staining of the follicle and of most extrafollicular lymphoid cells (immunoperoxidase technique on paraffin section). **D,** In the *lower right corner* is a portion of a reactive follicle with a mantle of small lymphocytes. The rest of the field is occupied by marginal zone cells.

Differential Diagnosis

As breast lymphoma is rare, that diagnosis is almost never suspected preoperatively. The clinical impression is usually carcinoma.[226] On pathologic grounds, the differential diagnosis includes carcinoma in cases of high-grade lymphoma and a reactive lymphoid infiltrate in cases of low-grade lymphoma. Lymphomas may be sampled via incisional or excisional biopsy, core needle biopsy, or fine-needle aspiration (**Fig. 59-13**). Careful attention to cytologic detail and to the discohesive nature of the lymphoid cells should lead to consideration of lymphoma. Diagnosis can then be confirmed by immunophenotyping. In the differential diagnosis of low-grade lymphoma and chronic inflammatory processes, in favor of EMZL are large numbers of B cells outside follicles, especially with the morphology of marginal zone cells, and monotypic immunoglobulin expression by B cells or plasma cells in the infiltrate. In distinguishing follicular hyperplasia from FL, criteria similar to those used in lymph nodes can be applied.

The uncommon reactive process known as *lymphocytic mastopathy, diabetic mastopathy,* or *autoimmune mastopathy* may be seen in patients with diabetes mellitus or immunologic disorders, or in women who are otherwise well. It usually presents as a palpable breast mass in young or middle-aged women.[236,237] Microscopic examination reveals a lobulocentric, sometimes also perivascular, lymphocytic infiltrate composed predominantly of B cells, sometimes with germinal-center formation, sometimes with lobular atrophy and sclerosis.[236,237] The tight perilobular distribution, lack of cytologic atypia, and lack of monotypic immunoglobulin help distinguish this disorder from lymphoma.

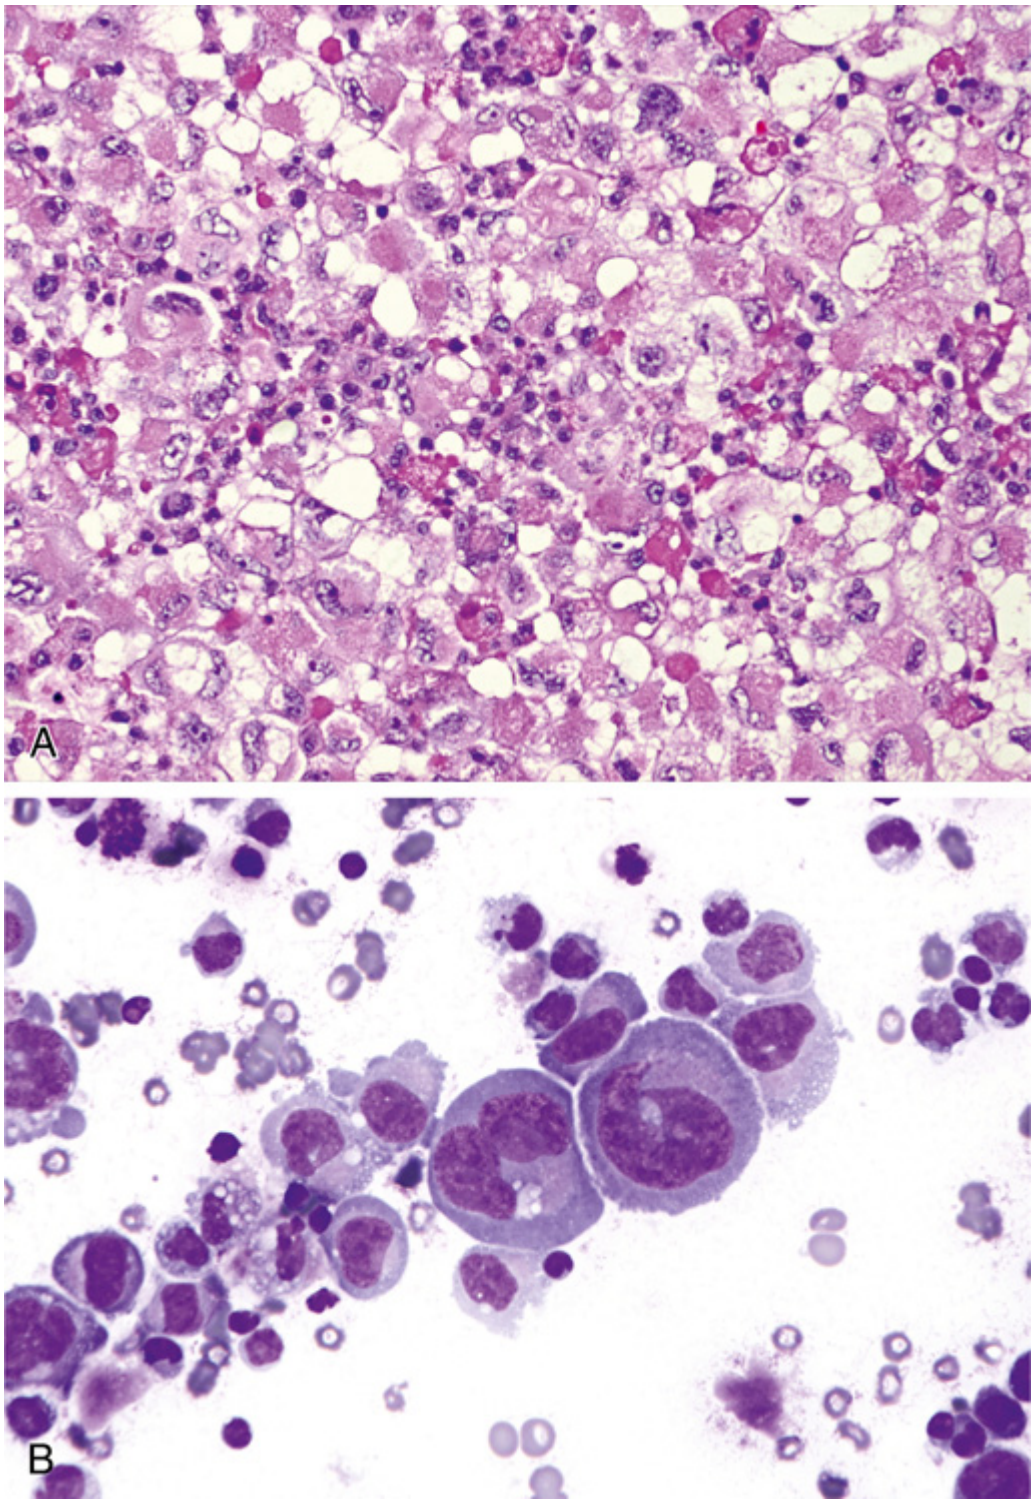

FIGURE 59-13 Breast implant associated anaplastic large cell lymphoma. **A,** Cell block from the seroma shows numerous large bizarre

cells with large oval or indented nuclei, prominent nucleoli and abundant pink cytoplasm. **B,** Wright stained smear shows large atypical Uni nucleated and binucleated neoplastic cells in a background of scattered small lymphocytes and histiocytes. Gastrointestinal Lymphomas

The GI tract is the most common primary extranodal site for lymphoma; 30% to 40% of all extranodal lymphomas[238] and 4% to 20% of all non-Hodgkin lymphomas arise in this site. The stomach is most often involved, followed by the small intestine, the colon, and then, rarely, the esophagus.[238-241] Predisposing factors include infection, in particular by *Helicobacter pylori*; celiac disease; and possibly inflammatory bowel disease. The GI tract is one of the most common sites for lymphoma in patients with congenital immunodeficiency syndromes (see **Chapter 53**), HIV infection, and iatrogenic immunosuppression (see **Chapter 54**).

Findings include pain, anorexia, weight loss, bleeding, obstruction, palpable mass, diarrhea, nausea, vomiting, fever, and perforation. Intussusception may occur with bulky ileocecal lymphomas.[242-247]

Gastric Lymphoma

The stomach is the primary site in 55% to 75% of GI lymphomas. Of gastric malignancies, 1% to 7% are lymphoma.[241,248] DLBCL is the

most common type, followed by EMZL (see **Chapter 18**). Other lymphomas are uncommon.

Gastric Diffuse Large B-Cell Lymphoma

Clinical Features

This is mainly a disease of older adults (median, 7th decade); younger adults are occasionally affected. There is a slight male preponderance.[249-251]

Pathologic Features

Gross examination reveals single or occasionally multiple large ulcerated or exophytic lesions that are usually transmurally invasive, sometimes associated with invasion of adjacent structures.[252] Microscopic examination reveals a diffuse proliferation of large cells with round, oval, irregular, or lobated nuclei, distinct nucleoli, and scant cytoplasm. An estimated one-third of cases have a concomitant component of EMZL consistent with large-cell transformation.[248] Immunophenotypic features are similar to DLBCL in other sites.[250,253]

Rearrangement of *BCL6* is more common, and *BCL2* rearrangement less common in gastric than in nodal DLBCL.[254] Despite the high frequency of t(11;18)(q21;q21)/*BIRC3*::MALT1 and trisomy 3 in EMZL, they are uncommon in DLBCL, implying that EMZL with these cytogenetic abnormalities are unlikely to undergo large-cell transformation.[253,255,256] Other trisomies (most often of chromosomes 12 and 18) are more common in DLBCL that have arisen through transformation of EMZL than in de novo large B-cell lymphomas.[257]

Staging, Treatment, and Outcome

In most cases (78%–95%), patients present with stage I or II disease.[249,250,253] A few have more distant spread to marrow, liver, or other sites.[248] Patients have been treated with surgery, radiation, chemotherapy, or a combination of these modalities. DLBCL associated with a component of EMZL is reported to have a better prognosis than de novo DLBCL.[249,250] Patients with stage Ie or IIe1 having a better outcome than those with IIe2 or higher.[250,253] A subset of gastric DLBCL is reported to respond to *H. pylori* eradication therapy.[256,258] Sensitivity or resistance to such therapy may be related to miRNA profile, mTOR pathway activation, and expression of Toll-like receptor 5.[259] An unknown factor may be overdiagnosis of DLBCL in cases of EMZL with "increased" large cells.

Differential Diagnosis

Poorly differentiated carcinomas may be composed of discohesive-appearing cells with little or no gland formation, and mimic DLBCL. Lymphoid cells may show artifactual vacuolar change and mimic signet ring cells. Immunohistochemical studies establish a diagnosis.

Small and Large Intestinal Lymphomas

The small intestine is the primary site in 15% to 35% of GI lymphomas.[241-243,248,260] The ileum/ileocecal region is more commonly affected than duodenum or jejunum.

Lymphoma accounts for ~25% of small intestinal neoplasms.[241] DLBCL is most common, followed by EMZL (including the distinctive subtype known as immunoproliferative small intestinal

disease [IPSID]) (**Chapter 18**), BL (**Chapter 23**), T-cell lymphomas (**Chapter 37**), mantle cell lymphoma (**Chapter 21**), and FL (**Chapter 17**).[241,242,247,252,260]

Of GI lymphomas, 7% to 20% arise in the colon.[243,260] Lymphoma accounts for 0.5% of colonic malignancies.[241,261] DLBCL is most common, followed by EMZL, mantle cell lymphoma, and rare cases of FL, BL, and peripheral T-cell lymphoma. Large intestinal lymphoma most often involves the cecum/ileocecal region, and the rectum is next most often involved; other portions of the colon are rarely affected.[241,262] Anal lymphomas are very rare; they are usually DLBCL.[263] Plasmablastic lymphoma may be primary in the large or small intestine, particularly the anal region.[264]

Intestinal Diffuse Large B-Cell Lymphoma

Clinical Features

Most patients are older adults, with a few cases occurring in younger adults or children. There is a slight male preponderance among adults; children are almost exclusively boys. Lymphoma in children is virtually only found in the ileocecal area.[245,247,261] Fewer than 1% of GI lymphomas arise in the setting of ulcerative colitis.[246] Ulcerative colitis–associated lymphomas, which are mostly DLBCL, are more often distally located in the colon, and almost always in sites of active inflammation. Compared with colonic lymphoma in the general population, in ulcerative colitis, lymphoma is more often multiple (38% vs. 10%).[265,266] These lymphomas have usually appeared in patients with long-standing ulcerative colitis,[265] although immunosuppressive/immunomodulatory therapy may accelerate lymphomagenesis.[267]

Pathologic Features

The gross and microscopic appearance is similar to gastric DLBCL (**Fig. 59-14**).[242,244,245,247,248] Some cases have a component of EMZL,[248] consistent with large-cell transformation of EMZL. The reported proportion of cases with an associated EMZL varies widely, from 10%[248] to >50% of DLBCL.[242,244,247] The immunophenotypic and genotypic features are similar to those of gastric DLBCL.

Staging, Treatment, and Outcome

In most cases, disease is confined to the intestine with or without regional lymph node involvement.[248] Treatment is usually surgical resection followed by chemotherapy. Five-year survival ranges from 25% to 67%.[252,255] DLBCL arising in association with EMZL may have a better prognosis than de novo DLBCL.[244]

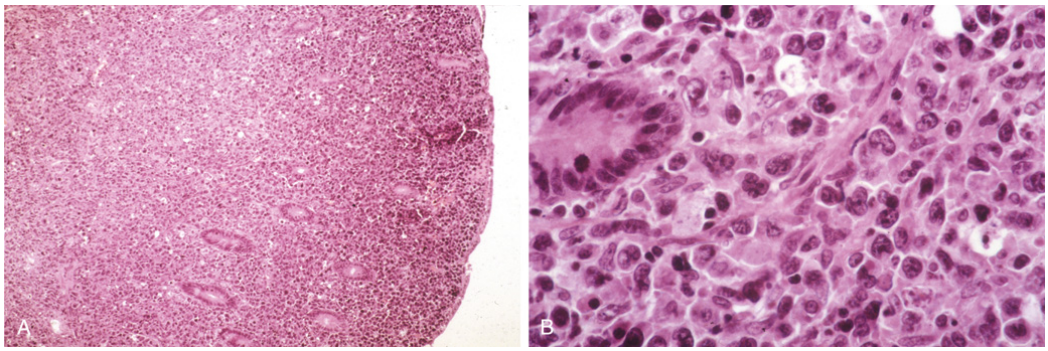

FIGURE 59-14 Diffuse large B-cell lymphoma, colon.A, Lymphoma invades deep into the wall of the bowel. **B,** The large, atypical neoplastic cells are highly irregular and often multilobated.

Mantle Cell Lymphoma

Mantle cell lymphoma is discussed in **Chapter 21**. In the GI tract, it often manifests as lymphomatous polyposis, involving long segments of bowel,[244,255] usually with mesenteric lymph nodal involvement,[255] often with widespread disease away from the GI tract. The pathologic features and prognosis are similar to that of other cases of mantle cell lymphoma.

Follicular Lymphoma

FL accounts for 2% to 13% of all primary GI tract lymphomas[238,268]; any portion of the GI tract may be involved,[269] but the duodenum is the most common site.[260,268,270,271] Most GI tract FL are duodenal-type FL, a variant of FL with distinctive clinical and pathologic features, including limited stage disease, low histologic grade, and excellent prognosis (**Chapter 17**).

Burkitt Lymphoma

Clinical Features

Three clinical variants of BL are traditionally recognized: endemic, sporadic, and immunodeficiency-associated; however, more recent data suggest BL is better subdivided based on EBV status than on epidemiologic subtype, as the presence or absence of EBV separates BL into discrete biological groups based on their molecular features.[1] Involvement of the ileocecal region is the most common manifestation of sporadic BL. Ileocecal disease may also be seen in a minority of endemic and immunodeficiency-associated BL. BL rarely affects other portions of the GI tract, including the stomach[248] and more distal portions of the colon. BL most often affects children and

young adults with a marked male preponderance.[242] In some cases, staging reveals disease beyond the GI tract.

Pathologic Features

The tumors are usually bulky exophytic lesions that may be associated with intussusception in the ileocecal area.[244] Histologic, immunophenotypic, and genetic features are similar to other sites. BL is discussed in **Chapter 23**.

T-Cell and Natural Killer–Cell Lymphomas

Gastrointestinal T-cell and NK-cell neoplasms are uncommon. Primary intestinal T-cell lymphomas, including enteropathy-associated T-cell lymphoma and monomorphic epitheliotropic intestinal T-cell lymphoma, and more recently recognized indolent disorders of the GI tract, including indolent clonal T-cell lymphoproliferative disorder of the gastrointestinal tract (ICC)/indolent T-cell lymphoma of the GI tract (WHO) (formerly *indolent T-cell lymphoproliferative disorder of the GI tract*)[1] and indolent NK-cell lymphoproliferative disorder of the GI tract (formerly *NK-cell enteropathy, lymphomatoid gastropathy*),[1,272] are discussed in **Chapter 37**. Other aggressive lymphomas, including anaplastic large-cell lymphoma and extranodal NK/T-cell lymphoma arising in the GI tract are described. Adult T-cell leukemia/lymphoma (HTLV1 positive) rarely presents with GI involvement. Acute-type and lymphoma-type adult T-cell lymphoma can involve the GI tract; involvement by chronic and smoldering forms of the disease is rare.[273]

Hodgkin Lymphoma

Clinical Features

Primary GI Hodgkin lymphoma is very rare, with fewer than 0.5% of cases of Hodgkin lymphoma arising in this site.[274] Given its rarity, careful evaluation to exclude other diseases is required. The differential diagnosis includes other aggressive lymphomas, poorly differentiated carcinoma, and EBV-positive mucocutaneous ulcer.[275]

Lymphomas of The Liver and Pancreatobiliary Tract

Hepatic Lymphomas

Clinical Features

Primary hepatic lymphoma is rare, representing an estimated 0.1% of hepatic malignancies, 0.4% of extranodal lymphomas, and 0.016% of all non-Hodgkin lymphomas.[276] Most patients are middle-aged and older adults with a wide age range (median, 50), and male-to-female ratio of ~2:1. Patients present with right upper quadrant or epigastric pain, nausea, vomiting, anorexia, or weakness. In ~50%, they have fever, night sweats, or weight loss, but jaundice is uncommon. Hepatomegaly is common.[277,278] Lactate dehydrogenase (LDH) is frequently elevated and hepatic transaminases may also be elevated; however, alpha fetoprotein (AFP) and carcinoembryonic antigen (CEA) levels are typically normal or only slightly elevated.[277-279] A minority of primary hepatic lymphomas are EMZL; hepatic EMZL is often an incidental finding.[276,280-282]

In up to 40% of cases, patients have another disorder such as an immunodeficiency, chronic infection, or autoimmune disease,[279,283] including hepatitis A, B, or C viral infection, HIV infection, organ

transplantation, systemic lupus erythematosus, Felty syndrome, autoimmune cytopenias, primary biliary cirrhosis, active tuberculosis, and others.[278-280,283-289] HIV-positive patients are younger and are almost exclusively males.[288]

Pathologic Features

In ~50% of cases, the lymphoma forms a large solitary mass. In most of the remainder, there are multiple nodules that may become confluent. In ~5% of cases, there is diffuse hepatic enlargement without a discrete mass.[277-279,283] Most lymphomas are DLBCL. The remainder are BL, EMZL, lymphoplasmacytic lymphoma, FL, and peripheral T-cell lymphoma.[277,278,284-287] Almost all lymphomas in HIV-positive patients have been DLBCL or BL.[288] Necrosis is common; sclerosis is infrequent. Lymphomas with diffuse hepatic enlargement may show prominent sinusoidal involvement.[277] Some of these are DLBCL; some are hepatosplenic T-cell lymphomas (see **Chapter 33**). Immunohistochemical features are similar to those seen in the same types of lymphoma in other anatomic sites.

EMZL has histologic features similar to those seen in other sites. The neoplastic B cells markedly expand the portal tracts, form intersecting broad serpiginous bands entrapping nodules of hepatocytes, and in areas produce a diffuse, confluent infiltrate. Neoplastic cells form LELs with bile duct epithelium.[276,280-282] Neoplastic cells are CD20 positive, CD5 negative, CD10 negative, and cyclin D1 negative. *BIRC3*::*MALT1* was reported in one case.[280]

Outcome

Most patients with hepatic EMZL have localized disease and are well on follow-up.[276,281,282,289,290] Prognosis for DLBCL patients is

relatively good.[279]

Differential Diagnosis

The finding of one or more hepatic lesions can suggest hepatocellular carcinoma or metastatic carcinoma. The combination of high LDH and normal CEA and AFP, particularly in a patient with an underlying immunologic abnormality, can suggest lymphoma.[279]

Lymphomas of the Gallbladder

Rare cases of primary gallbladder lymphoma are reported.[291-293] Most patients are older adults. Rare patients are HIV positive.[294] Concurrent cholelithiasis is common.[295] Patients present with symptoms that often mimic cholecystitis, cholelithiasis, or choledocholithiasis, such as right-upper quadrant pain,[292] nausea, vomiting, or rarely, jaundice.[291] Gross inspection shows mural thickening or one or more discrete tumor nodules. DLBCL and EMZL are most common.[291,293,295,296]

Lymphomas of the Extrahepatic Biliary Tree

Lymphoma occasionally involves porta hepatis lymph nodes and compresses the extrahepatic biliary tree, resulting in jaundice. Lymphoma arising primarily from the extrahepatic biliary tree is rare. Patients present with obstructive jaundice. The clinical and radiographic features often suggest carcinoma or sclerosing cholangitis. The walls of the bile ducts appear thickened. DLBCL is the most common type.[295,297,298]

Pancreatic Lymphomas

Clinical Features

Primary pancreatic lymphoma is rare, accounting for <0.2% of pancreatic malignancies,[299] and <0.7% of non-Hodgkin lymphomas.[68] Patients are adults (3rd–9th decade of age; mean, 60) with male-to-female ratio of approximately 2:1.[300-303] Rare patients are HIV positive,[301] but with this exception, patients have not had conditions predisposing to lymphoma. Patients complain of abdominal pain, anorexia, weight loss, nausea, or vomiting.[300,302] Patients are often jaundiced and may have a palpable mass.[300] The clinical diagnosis is often pancreatic adenocarcinoma. Prognosis is difficult to assess because this tumor is rare and patients have not been treated uniformly.

Pathologic Features

The tumors take the form of large masses (generally >6 cm), most often involving the pancreatic head, although the lymphoma may involve the body, tail, or entire pancreas.[300,302,303] The majority are DLBCL.[302,304] Rare cases of EMZL[303] and peripheral T-cell lymphoma have been reported.[302]

Differential Diagnosis

The main entity in the clinical differential diagnosis is pancreatic adenocarcinoma. Lymphomas are larger than most carcinomas.[304] On ERCP, lymphoma may compress or distort ductal structures, but generally does not invade their walls, in contrast to carcinoma.[300] Establishing a diagnosis requires tissue for pathologic examination.

Adrenal Lymphomas

Clinical Features

Primary adrenal lymphomas are rare.[305,306] Patients are adults (median, ~60), with a male-to-female ratio of 1.5:1 to 3:1.[305-308] Rare patients are HIV positive,[307] and a few have had autoimmune disorders,[307] but there are no known specific predisposing factors. Patients commonly present with loss of appetite, abdominal pain, fatigue, fever, night sweats, weight loss, or fatigue.[305-307] Most have elevated LDH, β2 microglobulin, CRP, ferritin, and ESR.[308] In 60% to 80% of cases, both adrenals are involved. Adrenal insufficiency is common among patients with bilateral adrenal involvement.[305-308] Disease is commonly detected outside the adrenals, but adrenal lesion(s) should be the predominant site for a diagnosis of primary adrenal lymphoma.[305-308]

Pathologic Features

Diagnosis can be established on needle biopsy or resected adrenal. The lymphomas typically form bulky adrenal masses (median, 7–8 cm).[305,307,308] DLBCL is by far the most common type, accounting for up to ~90% of cases.[307,308] DLBCL of non-GCB subtype is much more common than GCB subtype. Other lymphomas, including peripheral T-cell lymphoma and extranodal NK/T-cell lymphoma, are described, but are rare.[305,307]

Staging, Treatment, and Outcome

Improved diagnostic techniques and combination chemotherapy have together resulted in improved outcomes in some reports.[305,306] In one study, the 2-year survival of patients treated with chemotherapy was 84%.[307] In other series, however, survival is very poor.[308]

Urinary Tract Lymphomas

Lymphomas arising in the urinary tract (i.e., kidneys, ureter, urinary bladder, urethra) are uncommon, accounting for less than 5% of extranodal lymphomas, with an annual incidence of about 1 per 1,000,000. Renal lymphomas are more common than those in other sites.[309] The peak age incidence is in the 70s.[310] DLBCL is most common, followed by EMZL, then FL; rare cases of BL and other types have been reported.[310] An inferior prognosis is associated with male sex, older age, DLBCL histology, and high-stage disease, while EMZL has the best cause-specific survival.[310]

Renal Lymphomas

Clinical Features

Most cases reported as primary renal lymphoma are lymphomas presenting with renal involvement, although they are not necessarily confined to the kidney. Approximately 0.2% of non-Hodgkin lymphomas[311] and 0.7% of extranodal lymphomas present in the kidney.[68] Primary renal lymphoma accounts for <1% of all renal masses.[311] In contrast, secondary renal involvement by lymphoma is common: up to 30% of all non-Hodgkin lymphomas involve the kidneys secondarily.[311] Primary renal lymphoma patients are affected over a broad age range but most are middle-aged or older adults (mean age, 7th decade) with a male-to-female ratio of 1.7:1.9.[310-321] A few cases are reported in children.[315,321] A few patients have been HIV-positive[315] or iatrogenically immunosuppressed allograft recipients. Patients with other malignancies, autoimmune diseases, or other disorders are described,[312,313,315,322,323] but no risk factors specific for renal

lymphoma have been identified. Patients present with flank pain, loss of appetite, nausea, hematuria, weight loss, fever, renal insufficiency, or fatigue.[310,311,314-316,322,324] Rarely, the lymphoma is an incidental finding.[322]

Pathologic Features

Primary renal lymphoma is unilateral in approximately 75% to 95% of cases; the remainder are bilateral. Bilateral disease may be associated with renal insufficiency.[311,312,314-316,321,322] The lesions range from <5 cm to massive, with obliteration of the kidney. Frequently, the tumors invade adjacent tissues, including perinephric fat, psoas muscle, and even pancreas and duodenum. There may be vascular or ureteral encasement by the lymphoma. Occasional cases show extension into the renal vein and inferior vena cava, analogous to renal cell carcinoma.[314,315,322] Virtually all primary renal lymphomas are non-Hodgkin lymphoma, nearly all of which are B-lineage.[311,321] The most common renal lymphoma is DLBCL, accounting for slightly more than half of the cases. The remainder are of a variety of low-grade and high-grade types, including EMZL of mucosa-associated lymphoid tissue,[310,316,324] lymphoplasmacytic, follicular, lymphoblastic, BL, extranodal NK/T-cell, and very rare T-cell lymphomas,[310-312,314,315,317,319,321,320,322] including anaplastic large-cell lymphoma.[318] Lymphomas in HIV-positive patients have usually been DLBCL or BL.[315] Renal lymphoma in children is usually BL or, less often, lymphoblastic lymphoma.[315] Secondary renal lymphomas are less often DLBCL and are more often chronic lymphocytic leukemia/small lymphocytic lymphoma, compared with primary renal lymphoma.[325]

Staging, Treatment, and Outcome

Most patients presenting with renal lymphoma have more extensive disease on staging.[314-316,322] Five-year OS for all primary renal lymphoma patients is estimated at 64%, and that of DLBCL is reported as 58%.[321] The renal insufficiency found in some cases of bilateral renal lymphoma usually responds promptly to chemotherapy. A worse prognosis is associated with age over 60 years, male sex, advanced stage disease, and DLBCL or T-cell or NK-cell lymphoma.[311,321] Patients with EMZL have a better prognosis than other types of lymphoma.[321] Patients with bilateral disease tend to have a worse prognosis.[315,326]

Differential Diagnosis

Renal lymphomas, particularly when unilateral, may be mistaken clinically and radiographically for renal cell carcinomas.[313,315,323,324] Less often, they may mimic polycystic kidney disease,[315] soft tissue tumors,[327] inflammatory lesions,[327] or Wilms' tumor.[315] Lymphoma can generally be readily distinguished from the other entities on microscopic examination.

Ureteral Lymphomas

Lymphomas occasionally involve the ureters. Manifestations include abdominal or flank pain, nausea and vomiting, dysuria, hematuria, fever, renal insufficiency, hydronephrosis, and hydroureter.[328] In most cases lymphoma is widespread at presentation, or the ureters are secondarily involved via extension from retroperitoneal disease. Lymphomas confined to the ureters at presentation are exceedingly unusual but have been described.[328] The majority are DLBCLs. The

differential diagnosis includes idiopathic retroperitoneal fibrosis. Idiopathic retroperitoneal fibrosis can be associated with ureteral obstruction and a chronic inflammatory cell infiltrate, and retroperitoneal lymphomas can be associated with marked sclerosis and crush artifact, so differentiating the two may be difficult. Cytologic atypia of lymphoid cells and a diffuse, predominantly B-cell infiltrate support a diagnosis of lymphoma.

Lymphomas of the Urinary Bladder and Urethra

Clinical Features

Primary lymphomas of the urinary bladder are rare, accounting for <1% of bladder neoplasms.[309] Even less common are lymphomas arising in the urethra. Lymphomas arising in these sites share a number of clinical and pathologic features. They predominantly affect older adults, with a female preponderance.[310,329,330] Patients present with hematuria, urinary frequency, dysuria, recurrent urinary tract infections, or obstructive symptoms.[309,310,331] Analogous to the pathogenesis of EMZL at other sites, EMZL in the bladder may be related to prior inflammatory disease, with a number of patients having a history of chronic infectious cystitis,[330] or rarely chronic interstitial cystitis.[329]

Pathologic Features

The lesion(s) are single or occasionally multiple submucosal, exophytic, sessile nodules ranging from 1 to 15 cm. Sectioning usually reveals pale, firm tissue, although some tumors are soft and of variable color.[330] Most cases are EMZL.[331] Histologic features are similar to those in other sites. LELs may form in association with

cystitis cystica, cystitis glandularis, or surface epithelium.[330] Associated follicular cystitis is sometimes seen. A minority are DLBCL. These are mostly DLBCL, NOS, although rare EBV-positive DLBCLs are reported.[309] Some may represent large-cell transformation of an underlying EMZL. The most common urethral lymphomas are DLBCL and EMZL.[332-334] Cytogenetic analysis has only rarely been performed, but one EMZL arising in the bladder harbored a t(11;18), corresponding to *BIRC3*::*MALT1*. That lymphoma also had trisomies of chromosomes 3 and 18.[330]

Staging, Treatment, and Outcome

Nearly all patients have localized disease at presentation.[309,315,335,336] Prognosis is favorable because the lymphomas are often localized and responsive to therapy.[315,335,337] The outlook for patients with EMZL is excellent. Rare patients have had complete regression of EMZL with antibiotics alone.[330] DLBCL may behave in a more aggressive manner.

Differential Diagnosis

The main entity in the differential diagnosis of DLBCL is poorly differentiated carcinoma.[309,315] Low-grade lymphomas may be mistaken for chronic inflammatory disorders.[315] Urothelial carcinoma may have a dense inflammatory infiltrate or undifferentiated neoplastic cells and may mimic either low-grade or high-grade lymphomas.[338]

Male Genital Tract Lymphomas

Testicular and Epididymal Lymphomas

Clinical Features

Lymphoma accounts for ~5% of testicular tumors. Although uncommon, it is the most frequent testicular neoplasm in men over 50 years[339] (mean, late 50s or 60s in most series).[315,339-342] Children are rarely affected.[315,340,341,343,344] A few patients have been HIV positive,[345] but there is no known predisposing factor specific for testicular lymphoma. Patients typically present with a hard, painless scrotal mass; in a minority (14% in one series),[346] disease is bilateral. In a minority of cases, patients present with constitutional symptoms[315,345] or with symptoms related to extratesticular disease (e.g., neurologic abnormalities).[340] Lymphoma arising in the epididymis is much less common than testicular lymphoma, and lymphoma arising in the spermatic cord is extremely rare, but the clinical and pathologic features of lymphomas in these sites appear similar to those of testicular lymphoma.[340,347-352]

Pathologic Features

Orchiectomy specimens show a circumscribed, fleshy or firm, tan, gray, or white tumor ranging from a few millimeters to 16 cm in greatest dimension,[340] with a median of about 5 to 6 cm.[346,353] Lymphoma penetrates the tunica albuginea in about half of cases. The epididymis is often involved. The spermatic cord may also be involved.[340,353]

Lymphomas typically obliterate seminiferous tubules in at least some areas, with peripheral areas showing intertubular spread of tumor. In most cases, neoplastic cells invade seminiferous tubules, occupying the periphery of the tubules, displacing germ cells and

Sertoli cells centrally, or filling the tubules completely.[340] Nearly all are DLBCL.[339-341,345,354] Most are composed of centroblasts, but some DLBCLs show a predominance of immunoblasts or multilobated lymphoid cells.[340] Immunohistochemical analysis reveals pan–B-antigen expression and, in >75% of cases, a non-GCB immunophenotype.[346,355] BCL2 protein expression is frequent[354]; a subset of cases co-express MYC and BCL2 ("double-expressors").[353]

Genetic features are similar to those of primary CNS DLBCL; primary testicular DLBCL is included in the category of primary large B-cell lymphoma of immune-privileged sites.[1] Gains and translocations of *PD-L1* and *PD-L2* and loss of major histocompatibility complex genes are common changes.[30,354,355] Somatic mutations of *MYD88, CD79B,* and other NF-κB pathway genes are often found.[30,354,355] Loss, often biallelic, of *CDKN2A* is common.[30] Gene-expression profiling typically shows activated B-cell (ABC) DLBCL.[354] Deregulated PI3K signaling may also play a role in the pathogenesis of primary testicular DLBCL.[355] *BCL6* translocation is found in up to 50% of cases, but translocations of *BCL2* and of *MYC* are uncommon.[354]

Most primary testicular lymphomas in childhood are FL (see **Chapter 17**). These lymphomas are usually confined to the testis, express pan–B-cell antigens and germinal-center markers, but are typically BCL2 protein-negative, with no *BCL2* gene rearrangement.[344,356] The prognosis is excellent. Rare cases of primary testicular T-lymphoblastic lymphoma and B-lymphoblastic lymphoma are described in children and young adults.[357] Rare BLs are reported.[346]

Only a few peripheral T-cell lymphomas, including peripheral T-cell lymphoma, NOS, and anaplastic large-cell lymphoma have been described.[358,359] Infrequent primary testicular extranodal NK/T-cell lymphomas are described, mainly in Asian men.[346,360] They account for <1% of all extranodal NK/T-cell lymphomas.[360] These are aggressive, CD56-positive, EBV-positive lymphomas associated with a poor prognosis (see **Chapter 29**).

Staging, Treatment, and Outcome

Approximately 70% to 80% of patients with primary testicular DLBCL have limited-stage disease,[315,339,346] Testicular lymphoma has a relatively poor prognosis. When relapses occur, they often involve extranodal sites, most often CNS[339,341,361,362] but also the opposite testis, bone, lung, skin, and other sites; relapses may also involve lymph nodes.[339-341,345] The best outcomes are associated with orchiectomy and Adriamycin-based combination chemotherapy with rituximab. Because of the high risk of relapse in the CNS and opposite testis, some authorities suggest that intrathecal chemotherapy and irradiation of the opposite testis should be considered.[339,346]

A number of clinical and pathologic features affect the prognosis of DLBCL patients. Patients with localized, unilateral disease have a better outcome than those with widespread disease.[339,340,346,362] IPI score 0 to 2 versus 3 to 5 is associated with a better OS.[346] Sclerosis is associated with a favorable prognosis. In one study, lymphomas with sclerosis had a much better outcome than those without sclerosis (72% vs. 16% 5-year disease-free survival for all

patients; 90% vs. 34% 5-year disease-free survival for stage I patients).[340]

Differential Diagnosis

The most important entity in the differential diagnosis of testicular lymphoma is seminoma.[340] Compared with seminoma, lymphoma affects older patients, is more often bilateral, is more likely to involve the epididymis and spermatic cord, and is more likely to metastasize to sites such as bone or CNS.[340] Seminomas are composed of nests of neoplastic cells with abundant, glycogen-rich cytoplasm and uniform oval, euchromatic nuclei with prominent nucleoli delineated by fibrous septa that contain small lymphocytes and sometimes, granulomas. Seminomas express placental alkaline phosphatase (PLAP) and OCT4. Testicular DLBCL, particularly those with prominent sclerosis and large numbers of admixed non-neoplastic lymphocytes, may suggest a diagnosis of orchitis, including bacterial or viral infection or granulomatous orchitis. Acute inflammation with abscess formation and granulomas favors an inflammatory process. Other unusual entities, including plasmacytoma[363] and rhabdomyosarcoma, can occasionally enter the differential diagnosis, but clinical and histologic features, augmented by immunophenotyping, establish a diagnosis.

Prostatic Lymphomas

Clinical Features

Primary prostatic lymphoma accounts for 0.1% of all non-Hodgkin lymphoma and 0.09% of prostatic neoplasms.[364] In a large series of prostatic biopsies, transurethral resection specimens, and

prostatectomies, 0.17% of cases harbored primary prostatic lymphoma.[365] Secondary prostatic lymphoma is much more common than primary lymphoma; the most common type is chronic lymphocytic leukemia/small lymphocytic lymphoma.[331] Primary prostatic lymphoma affects patients over a broad age range, from childhood to advanced age (mean, ~60).[315,364,366-370] Patients present with bladder outlet obstruction, sometimes with hematuria.[365,366,368-371] Occasionally there is hydronephrosis,[368,370] sometimes with renal failure.[364] On physical examination, the prostate is usually diffusely enlarged and firm, but not as hard as with carcinoma.[367] Serum prostate-specific antigen (PSA) levels are often not significantly elevated, in contrast to carcinoma.[372] Patients are often thought to have benign prostatic hyperplasia,[315] and the diagnosis of lymphoma is only rarely suspected prospectively.

Pathologic Features

The lymphomas are of a variety of types, but DLBCL is most common.[366,367,372] Others have almost always been B cell lymphomas, including FL,[366,367] BL,[364,369,370] and several cases of EMZL of mucosa-associated lymphoid tissue (**Fig. 59-15**).[371,373] Microscopic examination reveals an atypical lymphoid infiltrate that is usually patchy, but that may be unifocal, extensive, and obliterative, or perivascular. Lymphoma infiltrates among fibromuscular bundles, and occasionally infiltrates glandular epithelium.[367]

Staging, Treatment, and Outcome

Staging has shown localized disease in most cases, although involvement of abdominal lymph nodes and of extranodal sites is not uncommon. The prognosis has been considered poor,[364] although patients treated in recent years with optimal therapy have had a better outcome.

Differential Diagnosis

The differential diagnosis includes poorly differentiated carcinoma and prostatitis. Even in poorly differentiated carcinoma, neoplastic cells at least focally form cords, cohesive sheets, and sometimes, glandular spaces. In the differential with prostatitis, a dense, monomorphous, cytologically atypical lymphoid infiltrate favors lymphoma.

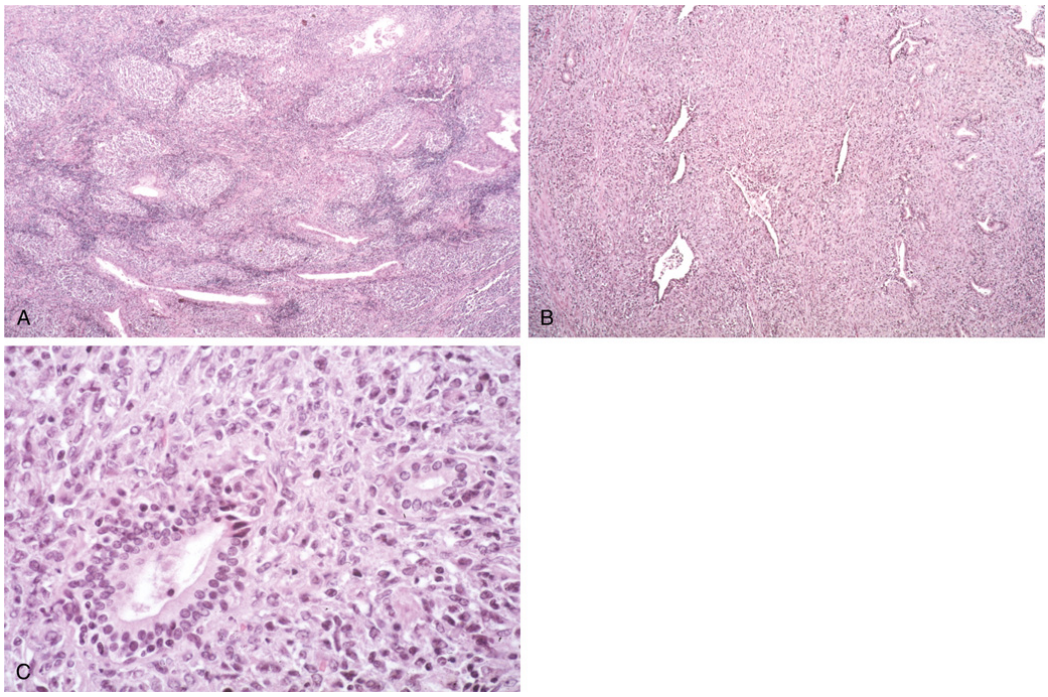

FIGURE 59-15 Diffuse large B-cell lymphoma with follicular lymphoma, primary in prostate. The lymphoma was an incidental finding at prostatectomy for carcinoma. **A,** An area of follicular lymphoma. **B,** Diffuse large B-cell lymphoma, adjacent to prostatic glands. **C,** An area of diffuse large B-cell lymphoma. Prostatic epithelial structures appear compressed and atrophic.

Lymphomas of The Female Genital Tract

Lymphomas only rarely arise in the female genital tract, accounting for 1.5% of all extranodal lymphomas, with an annual incidence of $0.44/10^6$ in the United States.[374] The ovaries are most commonly affected, followed by the uterine cervix, uterine corpus, vagina, vulva,

and fallopian tube. Nearly all are non-Hodgkin lymphoma of B-lineage, with DLBCL being the most common type throughout the female genital tract. A subset of lymphomas arising in the uterine cervix and vagina share features with primary cutaneous follicle center lymphoma and have an excellent prognosis.[375] T-cell lymphoma is very uncommon and Hodgkin lymphoma is vanishingly rare.[315,374,376] Except for rare lymphomas arising in the setting of HIV infection or iatrogenic immunosuppression,[377,378] or endemic BL, there are no known predisposing factors for the development of female genital tract lymphoma. Secondary involvement of the female genital tract by lymphoma arising elsewhere is more common than primary female genital tract lymphoma.

Ovarian Lymphomas

Clinical Features

Most series of ovarian lymphoma include cases in which patients present with ovarian involvement but may also have extraovarian disease.[379,380] Less than 1% of lymphomas present with ovarian involvement.[68,315,381] In countries where BL is endemic, however, approximately 50% of childhood ovarian malignancies are BL.[382] Patients range from 18 months to 74 years[315,383] (peak incidence, 4th–5th decade).[315,381,384] Lymphoma may present during pregnancy.[315] Patients commonly have abdominal pain and increasing abdominal girth, sometimes with ascites.[380,381,384,385] Constitutional symptoms are common.[380]

Pathologic Features

Ovarian lymphomas range from microscopic (representing incidental findings)[384] to 25 cm in diameter (mean, 8–14 cm).[315,380,384] They typically have an intact external surface, which may be smooth or nodular. Their consistency ranges from soft and fleshy to firm and rubbery, depending on the degree of associated sclerosis. On sectioning, the tumors are usually white, tan, or gray pink. A minority have hemorrhage or necrosis.[315,383,386] Very rare cases of lymphoma arising from a teratoma have been described.[387]

DLBCL is most common, followed by BL and FL.[380,381] Rare anaplastic large-cell lymphomas and B- and T-lymphoblastic lymphomas are reported.[376,384] In contrast to adults, who develop lymphomas of various types, younger patients almost always have diffuse, aggressive lymphomas.

Ovarian lymphomas may be associated with sclerosis, with tumor cells growing in cords and nests, simulating carcinoma.[382] Neoplastic cells may be elongated and grow in a storiform pattern, mimicking a sarcoma. Ovarian lymphomas may preferentially spare a peripheral rim of cortical tissue, corpora lutea, corpora albicantia,[315] and follicles,[383] but otherwise typically obliterate normal parenchyma. Ovarian lymphomas have immunophenotypic features similar to those of the same lymphomas in other sites.[315,384] In one study, ovarian FLs were divided into two groups. In the first, BCL2 was negative or weakly expressed, *IGH*::*BCL2* fusion was absent, the lymphomas were grade 2 or grade 3A, and when stage was known, the lymphomas were confined to one ovary. In the second group, all lymphomas were low-grade, BCL2 was strongly expressed, *IGH*::*BCL2* fusion was present, and most had widespread

disease. Outcome was more favorable for patients from the first group.[388]

Staging, Treatment, and Outcome

One or both ovaries are involved with approximately equal frequency.[383,386] Extraovarian spread is found in most cases, commonly to pelvic or paraaortic lymph nodes and occasionally to peritoneum, other portions of the female genital tract, or more distant sites.[315,381] Ovarian lymphoma has been considered prognostically unfavorable, although with aggressive combination chemotherapy the prognosis appears similar to that of nodal lymphomas of comparable stage and histologic type.[379,384] Patients with bilateral ovarian involvement, widespread disease on staging, and larger ovarian masses may have a worse prognosis.[380]

Differential Diagnosis

The differential diagnosis of ovarian lymphoma includes dysgerminoma, undifferentiated carcinoma, metastatic carcinoma (particularly from the breast),[383] primary small cell carcinoma, adult granulosa cell tumor,[385] sarcoma, and myeloid sarcoma.[315] Attention to cytologic detail and familiarity with the spectrum of histologic features of ovarian lymphoma are helpful in establishing a diagnosis.

Fallopian Tube Lymphomas

Primary fallopian tube lymphoma is very rare, but unilateral and fewer bilateral cases are described.[315,389-391] EMZL, DLBCL, and FL are reported. Among patients with ovarian lymphoma, secondary

tubal involvement is found in >25%. DLBCL and BL are most common in this setting.[383,392]

Uterine Lymphomas

Clinical Features

Malignant lymphoma arising in the uterus is rare; <1% of extranodal lymphomas arise in this site.[68] Lymphomas arise much more often in the cervix than in the corpus, with a ratio of as high as 10:1 in one series.[393] Ages range from 20 to 80 years,[394] with a median in the 5th decade.[394-396] Patients usually present with abnormal vaginal bleeding.[315,392,394,395,397] Dyspareunia, or perineal, pelvic, or abdominal pain are less common. Constitutional symptoms are unusual.[315,396] Only a minority of cervical lymphomas yields a positive cervical smear, presumably because lymphomas are not usually ulcerated.[398]

Pathologic Features

Cervical lymphomas usually produce bulky lesions readily identifiable on pelvic examination.[397] The classic appearance is diffuse, circumferential enlargement of the cervix ("barrel-shaped" cervix). The lymphoma may also form a discrete submucosal tumor,[394] a polypoid or multinodular lesion,[394,399,400] or a fungating, exophytic mass; ulceration is unusual.[394] The tumors are fleshy, rubbery, or firm. They are usually homogeneous in color and white-tan to yellow.[394] Extensive local spread to vagina, parametria, or even pelvic side walls is common.[394,399] Ureteral obstruction with hydronephrosis is common.[315,394] Lymphomas of the uterine corpus are usually fleshy or soft, pale gray, yellow, or cream colored. They

may form a polypoid mass or diffusely coat the endometrium, sometimes with deep invasion of the myometrium.[315,394]

The majority of lymphomas are DLBCL; they may be of GCB or non-GCB type (**Fig. 59-16**).[392,393,397,400] FL is next most common (**Fig. 59-17**). A few cases of BL[376] and small numbers of EMZL[315,376,392,393,401,402] are reported. Also described are rare B-lymphoblastic lymphomas,[376] peripheral T-cell lymphomas,[403,404] and extranodal NK/T-cell lymphomas.[392]

In the cervix, there is often a band of uninvolved tissue just beneath the epithelium, and the overlying epithelium is usually intact. Deep invasion of the cervical wall is common. Perivascular spread of tumor is common in FL.[394] Cervical lymphomas are frequently associated with prominent sclerosis,[400] which may be associated with a cord-like arrangement or spindle-shaped tumor cells.[394] Crush artifact is often prominent, hindering evaluation.[315,376,394,400]

A recent study described a series of follicle center lymphomas arising in the cervix or vagina with an excellent prognosis (5-year OS, 100%) and noted similarities to primary cutaneous follicle center lymphoma. The pattern was follicular or diffuse, with a frequent component of large centrocytes, lack of BCL2 expression and of *BCL2* rearrangement in nearly all, frequent mutation of *TNFRSF14,* lack of *CREBBP* and *KMT2D* mutations (which are common in nodal FL), presentation with localized disease, and absence of progression on follow-up.[375]

The rare primary endometrial EMZL have distinctive features.[401,402,405,406] They usually arise in postmenopausal women, often as an incidental finding. They are composed of nodules

of small, monotonous lymphoid cells with clear cytoplasm scattered in the endometrium, typically with, at most, superficial myometrial invasion. The immunophenotype is similar to that of EMZL in other sites, except that CD43 is typically co-expressed by neoplastic B cells. One case had CD5 expression.[401]

Staging, Treatment, and Outcome

Although most uterine lymphomas are bulky and locally invasive, the majority are localized.[315,392] The prognosis of cervical DLBCL treated with immunochemotherapy is excellent.[397] There is not enough information to draw definite conclusions about the prognosis of the rare endometrial lymphomas. However, those with localized disease tend to do well, while those with advanced disease presenting with endometrial involvement tend to fare poorly.[394,402] Endometrial EMZL has an excellent prognosis.[405]

Vaginal and Vulvar Lymphomas

Lymphoma rarely arises in the vagina,[315,396,407] and even less often in the vulva.[315,378,408,409] Patients are affected over a wide age range. They present with vaginal bleeding, discharge, pain, dyspareunia, urinary frequency, or a mass. Surface epithelium is usually intact. Papanicolaou smears are generally negative.[410] Nearly all are DLBCL,[315,376,407,409,411] but rare cases of FL,[376,394] BL,[412] lymphoplasmacytic lymphoma,[376] and T-cell lymphoma[315,410] are reported. The vulva may also be affected by a variety of primary cutaneous lymphomas.[413,414] Vaginal lymphomas are often associated with sclerosis. Vaginal lymphoma usually presents with localized disease and has a favorable prognosis.[396,407,410,415] Vulvar

lymphomas are relatively aggressive, but occasional patients have long disease-free survival.

Differential Diagnosis of Lower Female Genital Tract Lymphoma

Common entities in the differential diagnosis are poorly differentiated carcinoma and a reactive lymphoid infiltrate.[315,394] Unlike carcinoma, which tends to invade with obliteration of normal structures, lymphoma tends to infiltrate around them, with relative preservation of endometrial and endocervical glands and sparing of the most superficial subepithelial stroma.[315] Adjacent in situ squamous or adenocarcinoma favors carcinoma.

Marked chronic inflammation is common in the cervix, and occasionally seen in the endometrium, vagina, and vulva; infrequently it is so dense and extensive that it raises the question of lymphoma (so-called “lymphoma-like lesion”).[416] In favor of an inflammatory process are absence of a mass, superficial location, association with erosion or ulceration of the overlying epithelium, and polymorphous composition with follicle center cells, immunoblasts, small lymphocytes, plasma cells, and neutrophils. Marked chronic inflammatory processes involving the endometrium are generally associated with areas of more typical-appearing chronic endometritis. Rarely, there is associated EBV infection.[417] In contrast, lymphoma usually produces a mass with extension into adjacent structures. Lymphomas tend to invade deeply, spare a narrow subepithelial zone, be composed of a monomorphous population of lymphoid cells (often with sclerosis), and spread in proximity to blood vessels.[417]

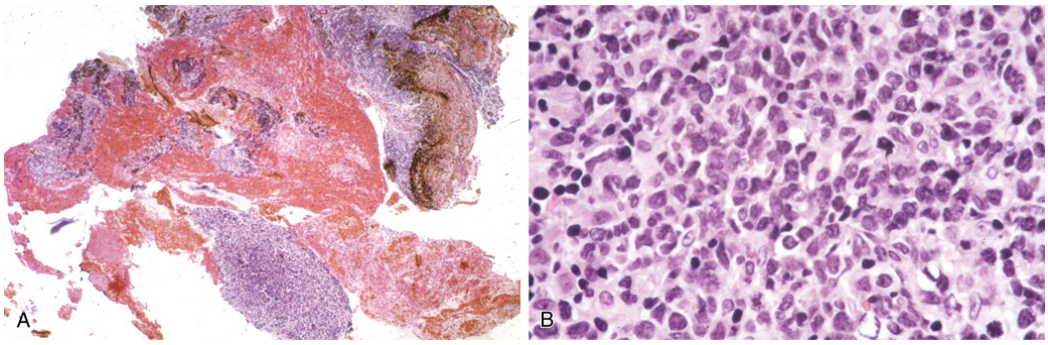

FIGURE 59-16 Diffuse large B-cell lymphoma, uterine cervix.A, Curetted fragments of lymphoma admixed with blood. **B,** Higher power shows large atypical lymphoid cells with irregular nuclei.

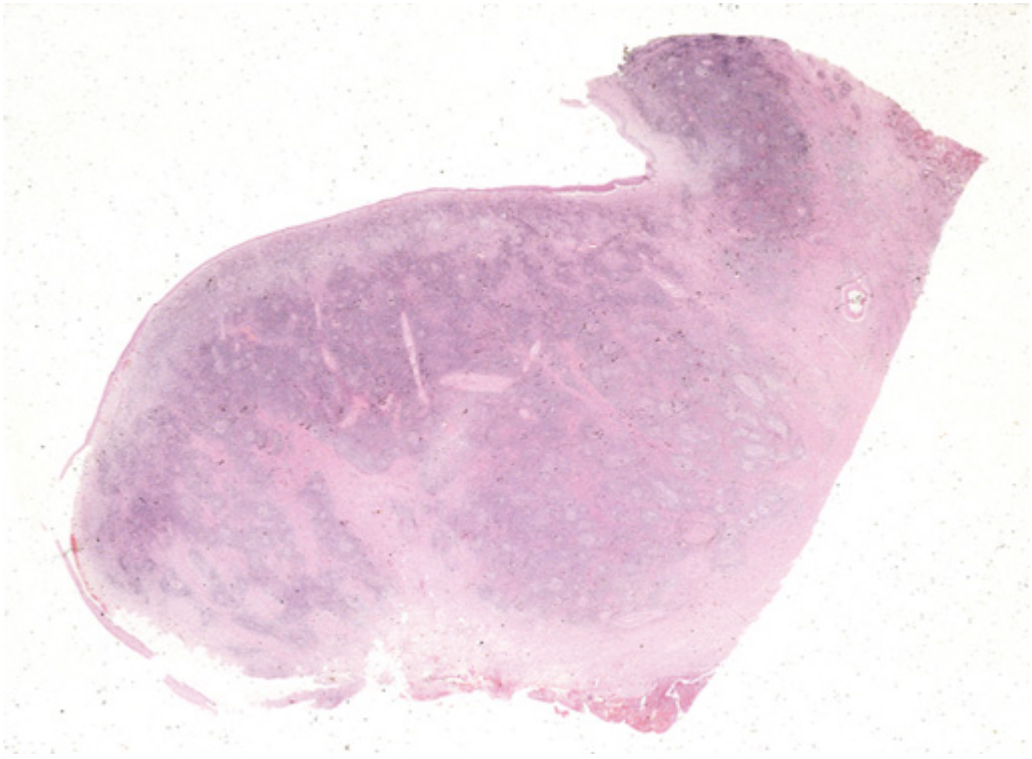

FIGURE 59-17 Follicular lymphoma, uterine cervix, whole mount. Neoplastic follicles invade deep into the wall of the cervix.

A rare entity that may suggest lymphoma is leiomyoma with lymphoid infiltration (i.e., uterine leiomyomas with a moderate-to-dense infiltrate of small lymphocytes with scattered larger lymphoid cells), occasionally with germinal centers, plasma cells, and rarely, eosinophils. The inflammatory cells are largely confined to the leiomyoma. The polymorphous nature of the infiltrate and its confinement to the leiomyoma help distinguish it from lymphoma. In all reported cases of leiomyoma with lymphoid infiltration, follow-up has been uneventful.[418]

Lymphomas of Bone

Clinical Features

Primary lymphomas of bone are defined as lymphomas arising in bone, with or without extension into adjacent soft tissue, without lymphoma elsewhere on staging. Some authorities accept cases with regional lymph node involvement, but not with more distant spread.[419-421] Primary lymphomas of bone account for 3% of primary osseous neoplasms,[422,423] <1% of all lymphomas,[419,424] and ~5% of extranodal non-Hodgkin lymphomas.[68] Among children, primary lymphomas of bone account for a higher proportion of non-Hodgkin lymphomas (2.8%–4.2%).[425] Etiology is unknown. Most patients have no known predisposing conditions, but rare patients with Paget disease of bone who developed primary lymphoma of bone are described.[426]

There is a slight male preponderance. Patients may be of any age, from young children to the elderly; however, most are adults (median, 5th–6th decades).[419,423,424,427-433] Patients present with localized pain.[419,420,423-425,434] A minority also have swelling or a palpable mass or fracture.[422,424,427,434] Patients rarely present with constitutional symptoms.[424,425] Most commonly affected are the long bones of the extremities, with the femur involved most often, followed by the tibia and the humerus. Next most common are the flat bones of the shoulder and pelvis, followed by the remainder of the axial skeleton and the cranial and jaw bones.[423,424,427,430,431,434] Small bones of the hands and feet are rarely involved.[430] Disease is usually monostotic; in a minority of cases it is polyostotic.[419,420,425,427,431,434-437] Radiographic

examination usually shows a lytic lesion with ill-defined margins. In a minority of cases the appearance is blastic or mixed blastic and lytic. Radiographs may demonstrate pathologic fracture or soft tissue extension with an associated periosteal reaction.[419,422,423,429,434]

Pathologic Features

In adults, nearly all primary lymphomas of bone are DLBCL. Many are composed of cells with large irregular or multilobated nuclei; others are composed of centroblasts with oval nuclei, immunoblasts, or bizarre pleomorphic cells.[423,428-432,434,438] Neoplastic cells may become elongated and resemble spindle cells.[423,439] Also reported are rare cases of BL, anaplastic large-cell lymphoma (ALK positive and ALK negative, **Fig. 59-18**),[438,440] B-lymphoblastic lymphoma,[441,442] low-grade lymphomas, peripheral T-cell lymphoma, NOS,[419] and adult T-cell lymphoma/leukemia.[443] Rare cases of CHL presenting in bone are reported.[422,444-446] Staging reveals lymph node involvement in most cases,[445] but some appear to represent true primary osseous Hodgkin lymphoma.[444,446]

In children, ~40% of bone lymphomas are lymphoblastic lymphoma, 10% are BL, and 50% are DLBCL. The DLBCLs may have a GCB or non-GCB-cell immunophenotype.[437,447] Like other extranodal DLBCL, and in contrast to nodal DLBCL, the *BCL2* translocation is uncommon.[431,437] PI3K/AKT/mTOR pathway activation is proposed to play a role in the pathogenesis of DLBCL with a non-GCB–like immunophenotype.[447]

Staging, Treatment, and Outcome

DLBCL is often localized; lymphoblastic lymphoma is more often associated with multifocal osseous disease and higher stage.[425,442,448] Staging may reveal more widespread disease, most often involving regional lymph nodes or other bones.[428,437] Primary lymphoma of bone has a better prognosis than other bony malignancies. In patients with localized disease who are optimally staged and treated, 5-year disease-free survival may be as high as 90%.[424,448] An inferior prognosis is associated with higher stage disease, polyostotic disease, extension into soft tissue, primary tumor in the pelvis or spine, and older age. Lymphomas arising in long bones have a better prognosis.[424-426,428,429,434] Among DLBCLs, a better outcome has been associated with treatment with chemotherapy,[426] cases composed of large irregular cells or multilobated cells,[429,432,438,449] and a GCB-like phenotype.[437]

Relapses are most often to other bones and lymph nodes.[419,420,423,431,438,448] Less common sites of relapse include adjacent soft tissue, lung, bone marrow, and CNS.[423,438] Patients with lymphoblastic lymphoma may progress to acute lymphoblastic leukemia.[425,448]

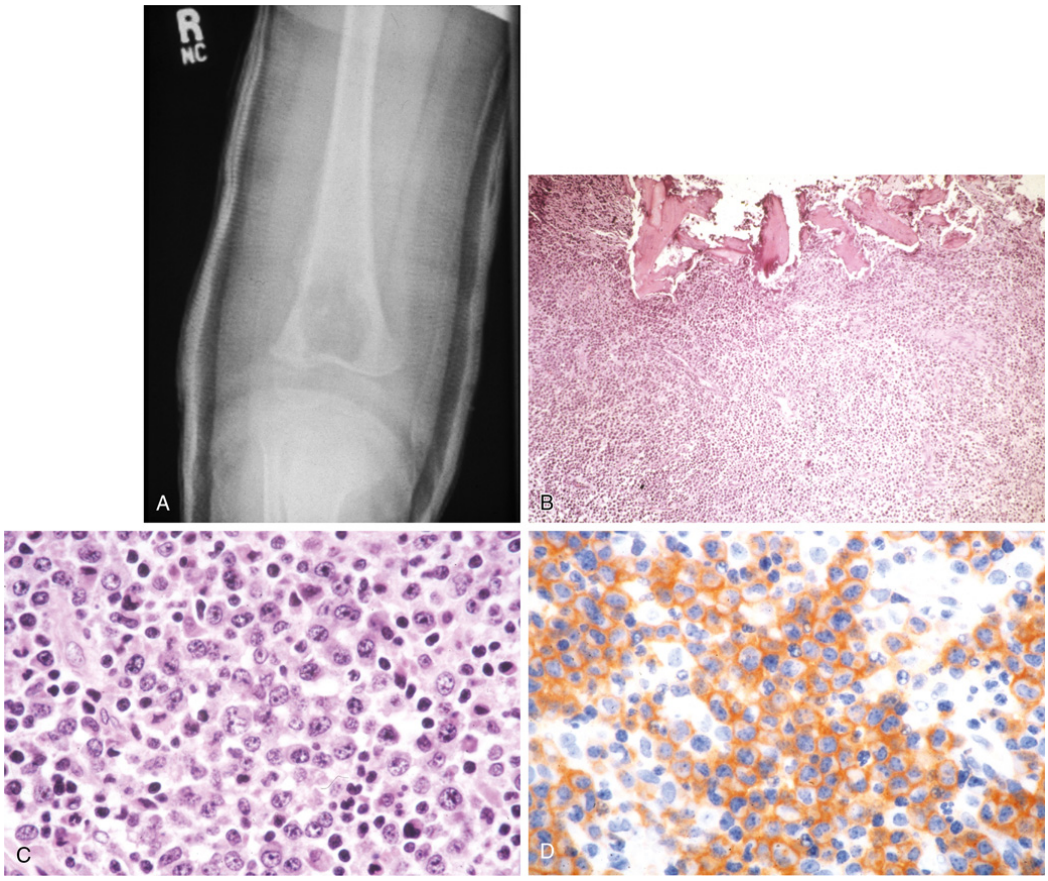

FIGURE 59-18 ALK-positive anaplastic large cell lymphoma in a child.A, A destructive lytic lesion involves the metaphysis of the distal femur. **B,** The lymphoma is associated with bony destruction. **C,** The lymphoma is composed of large, atypical cells with oval or indented nuclei and pink cytoplasm. **D,** Neoplastic cells are intensely positive for CD30 (immunoperoxidase technique on a paraffin section). ALK was also positive *(not shown)*.

Differential Diagnosis

Rendering the correct diagnosis may be difficult because of associated fibrosis, crush artifact, overdecalcification, small specimen size, and admixed reactive cells. The differential diagnosis of bone lymphoma is broad, and includes other types of neoplasms and inflammatory processes.[422,425,429,430,433] Bone lymphoma can be misdiagnosed as an inflammatory process such as chronic osteomyelitis[422,425,433] or as a simple fracture[422] if there is a large reactive component and if neoplastic cells are present in small numbers or are not well preserved. Because in some cases, particularly in association with sclerosis, neoplastic cells are elongate, spindle cell sarcoma can enter the differential.[423,433,439] Exuberant reactive woven bone may cause misinterpretation as osteosarcoma. Langerhans cell histiocytosis and poorly differentiated plasmacytoma may enter the differential diagnosis, but cytologic features and immunophenotyping help establish a diagnosis. Myeloid sarcoma can mimic lymphoma, especially lymphoblastic lymphoma. If the myeloid sarcoma has a component of monocytes with irregular nuclei, the appearance can resemble diffuse DLBCL with large irregular or multilobated cells. Lymphoma may also raise consideration of a small round cell tumor, but Ewing sarcoma has cytoplasmic glycogen and a more cohesive growth pattern, and less pleomorphic nuclei than lymphoma. Neuroblastoma may present with bony metastases. The tumor cells may form rosettes; they are pear-shaped or carrot-shaped cells with denser chromatin than lymphoma. The differential of the rare Hodgkin lymphoma involving bone includes acute or chronic osteomyelitis, depending on the composition of the reactive population, particularly if large neoplastic cells are present in small numbers.[444]

Pearls and Pitfalls

- The types of lymphomas encountered in extranodal sites differ to some extent from those encountered in lymph nodes. These lymphomas vary by the specific extranodal site. Familiarity with the types of lymphomas arising in different extranodal sites facilitates diagnosis.
- Carcinomas are much more common than lymphomas in many extranodal sites, and this may lead to failure to consider a diagnosis of lymphoma. Lymphoma should be considered when the specimen shows an undifferentiated-appearing malignant neoplasm.
- In certain extranodal sites, such as bone and the lower female genital tract, crush artifact may be a significant barrier to establishing a diagnosis. In such cases, pathologists should request more tissue until an adequate specimen is obtained.
- Certain types of extranodal lymphomas tend to occur in certain age groups or ethnic groups or in association with an underlying immunodeficiency or autoimmune disorder. Clinical correlation is important in establishing the correct diagnosis.
- Infectious mononucleosis can mimic both classic Hodgkin lymphoma and diffuse large B-cell lymphoma; infectious mononucleosis should be considered in the differential diagnosis of atypical lymphoid proliferations in Waldeyer's ring, especially in young patients.

- Certain extranodal diffuse large B-cell lymphomas, such as primary effusion lymphoma and plasmablastic lymphoma, are characteristically CD20 negative. If morphology suggests lymphoma and CD20 is negative, the possibility of lymphoma should not be excluded until immunostaining with a broader panel of markers is performed.

CD4

in blastic plasmacytoid dendritic cell neoplasm, **1024**

in intestinal T-cell lymphoma, **748–749**, **752t**

in small-to-medium-sized T-cell lymphoproliferative disorder, **768**

in T-cell neoplasms, **53**

CD4-positive cells, in severe mosquito bite allergy, **616**

CD4-positive small/medium T-cell lymphoma, cutaneous, **800–801**

clinical course of, **800**

clinical features of, **800**, **800f**

definition of, **800**

differential diagnosis of, **801**

epidemiology of, **800**

etiology of, **800**

genetics of, **800**

immunophenotype of, **801**, **802f**

morphology of, **800**, **801f**

synonyms and related terms to, **800**

CD4-positive T cells, in follicular helper T-cell, **709**, **711f**

CD5

in diffuse large B-cell lymphoma, **452**, **457f**, **459b**, **466**

in mantle cell lymphoma, **433**

CD7

in mycosis fungoides, **764**

in T-cell lymphoblastic leukemia/lymphoma, **817**

CD8

in EBV-associated hemophagocytic lymphohistiocytosis, **612–613**

in mycosis fungoides, **764**

in refractory celiac disease, **744**, **746f**

in T-cell neoplasms, **53**

CD8-positive T cells, in T-cell large granular lymphocytic leukemia, **647–648**

CD10

in B-cell differentiation, **142**

in diffuse large B-cell lymphoma, **451–452**

in follicular helper T-cell, **708f**, **709–711**

in follicular lymphoma, **357**

in post-therapy bone marrow evaluation, **1178**

CD11c, in hairy cell leukemia, **331–333**, **333t**, **335–336**

CD15

in classic Hodgkin lymphoma, **573**, **574f**

in lymphocyte-predominant cells, **548t–549t**

in peripheral T-cell lymphoma, not otherwise specified, **691f**

CD19

in B-cell differentiation, **142**

in B-cell neoplasms, **46**

in lymphocyte-predominant cells, **548t–549t**

CD20

in B-cell neoplasms, **46**

in classic Hodgkin lymphoma, **573–575**

in diffuse large B-cell lymphoma, **451**

in infectious mononucleosis, **463**, **467f**

in lymphocyte-predominant cells, **547–550**, **548t–549t**, **549f**

in lymphoplasmacytic lymphoma and Waldenström macroglobulinemia, **315–321**, **319f**

in peripheral T-cell lymphoma, not otherwise specified, **688**, **690f**

in splenic marginal zone lymphoma, **339**

CD21

in follicular helper T-cell, **708f**, **709–711**

in follicular lymphoma, **370**

CD22, in B-cell neoplasms, **46**

CD23, in follicular lymphoma, **370**

CD25

in adult T-cell leukemia/lymphoma, **669–670**

in hairy cell leukemia, **333t**

CD30

in anaplastic large cell lymphoma, **719**, **723f**

in classic Hodgkin lymphoma, **573**, **574f**

in diffuse large B-cell lymphoma, **452**, **462**

in lymphocyte-predominant cells, **548t–549t**, **551**

in mycosis fungoides, **764**

in peripheral T-cell lymphoma, not otherwise specified, **688–689**, **691f**

CD34

in B-cell differentiation, **149**

in B-cell lymphoblastic leukemia/lymphoma, **809**

CD38, in chronic lymphocytic leukemia/small lymphocytic lymphoma, **288–289**, **292f**

CD38 therapy, technical issues related to, in multiple myeloma, **525–526**, **526t**, **527f**

CD40, in lymphocyte-predominant cells, **548t–549t**, **551**

CD40L

deficiency, **1088–1090**

in hyper IgM type 1 syndrome, **1088–1090**, **1091f**

CD43

in anaplastic large cell lymphoma, **719**, **723f**

in mantle cell lymphoma, **433**

CD44H, in lymphocyte-predominant cells, **548t–549t**, **551**

CD45

in B-cell lymphoblastic leukemia/lymphoma, **59**

in classic Hodgkin lymphoma, **573**, **574f**

in lymphocyte-predominant cells, **548t–549t**

CD56

in blastic plasmacytoid dendritic cell neoplasm, **1024**

in extranasal NK/T-cell lymphoma, **628–629**

in multiple myeloma, **524–525**

in mycosis fungoides, **764**

CD57, in T-cell large granular lymphocytic leukemia, **647–648**

CD68, in blastic plasmacytoid dendritic cell neoplasm, **1025**

CD70, in lymphocyte-predominant cells, **547–550**, **548t–549t**

CD74, in lymphocyte-predominant cells, **548t–549t**

CD79A (MB1), in lymphocyte-predominant cells, **548t–549t**

CD80, in lymphocyte-predominant cells, **548t–549t**

CD86, in lymphocyte-predominant cells, **548t–549t**

CD103, in hairy cell leukemia, **333t**

CD123, in hairy cell leukemia, **333t**

CD138

in lymphocyte-predominant cells, **548t–549t**, **550**

in lymphoplasmacytic lymphoma and Waldenström macroglobulinemia, **315–321**

CD200, in hairy cell leukemia, **333t**

CD303, in blastic plasmacytoid dendritic cell neoplasm, **1025**

CDw75 (LN1), in lymphocyte-predominant cells, **548t–549t**

CEBPA mutations

in acute myeloid leukemia, **97**

bZIP, acute myeloid leukemia with, **903**

CEBPA zipper domain, **870**

Celiac disease, refractory, **738t**, **740f**, **744–749**

clinical course of, **738t**, **748**

clinical presentation of, **738t**, **745**

definition and classification of, **744**

epidemiology of, **744–745**

etiology of, **745**

histopathology of, **745**, **746f–747f**

immunophenotypic and molecular analysis of, **738t**, **745–747**, **746f–748f**

pathogenesis of, **748–749**

Cell cycle deregulation, in mantle cell lymphoma, **438**

Cell cycle proteins, in lymphocyte-predominant cells, **548t–549t**, **551**

Cell ploidy, alterations of, **109–110**, **109t**

Cell survival, in mantle cell lymphoma, **440**

Centerin (GCET-1), in follicular lymphoma, **368–369**

Central nervous system

adult T-cell leukemia/lymphoma in, **669**

Burkitt lymphoma in, **485**

chronic lymphocytic leukemia/small lymphocytic lymphoma in, **286**, **287f**

Langerhans cell histiocytosis in, **1056–1058**

mantle cell lymphoma in, **428**

posttransplant lymphoproliferative disorders in, **1108**

primary lymphoma of, **1229–1232**, **1231f**

Centroblasts

in B-cell lymphomas, **20f**

in dark zone, **139**

in diffuse large B-cell lymphoma, **450**, **452f**

in follicular hyperplasia, **159–160**, **162f**

in follicular lymphoma, **21**, **22f–23f**, **352**, **354f**, **357**

in primary cutaneous follicle center lymphoma, **403–406**, **406f**

Centrocytes

in B-cell lymphomas, **18**

in follicular hyperplasia, **159–160**

in follicular lymphoma, **21**, **22f–23f**, **352**, **354f**, **357**

in primary cutaneous follicle center lymphoma, **403–406**, **406f**

Centromere, **108–109**

Cerebrospinal fluid (CSF), lymphoplasmacytic lymphoma and Waldenström macroglobulinemia in, **315**, **319f**

Ceroid histiocytosis, **1227**

Chédiak-Higashi syndrome, neutropenia in, **234t**, **235–236**, **235f**

Chemotherapy

for adult T-cell leukemia/lymphoma, **672**

for extranasal NK/T-cell lymphoma, **633–634**

for Hodgkin lymphoma, **577**

for primary cutaneous anaplastic large cell lymphoma, **786**

for T-cell prolymphocytic leukemia, **661**

Children

mycosis fungoides in, **766–767**

neutropenia in, acquired, **230**

nodal marginal zone lymphoma in, **420**

Chimeric antigen receptor (CAR), **38**

CHK2 gene, in mantle cell lymphoma, **439–440**

Chlamydia psittaci, ocular adnexal MALT lymphoma and, **387**

Chloroacetate esterase, **1028**

Chondroblastoma, **1194**

Chondroma, **1194**

Chondromyxoid fibroma, **1194**

Chromatin, **108–109**

Chromogenic in situ hybridization (CISH), **38–40**

Chromoplexy, **111**

Chromosomal aberrations, **109**

in hematologic neoplasms, **108–132.e9**

pearls and pitfalls in, **132b**

types of, **108–111**
in myelodysplastic syndromes, **121t**
Chromosomal abnormalities
acquisition of, **118–120**
in hematologic malignancies, **119t–120t**
clinical relevance of, **118–132**, **120t**
Chromosomal instability, **109**
Chromosome fragility testing, for Fanconi anemia, **246–248**
Chromosome-specific centromeric probes, **112**
Chromosomes, **108–109**
human, **108–109**
Chromothripsis, **111**
Chronic active Epstein-Barr virus infection, **613–616**
cells of origin of, **615**
clinical features of, **614**
definition of, **613–614**
diagnostic features of, **613b**
differential diagnosis of, **616**, **616b**
epidemiology of, **614**
genetics of, **614–615**
grading of, **615**

immunophenotype of, **614**

morphology of, **614**, **615f**

pathophysiology of, **614**

prognosis and predictive factors of, **615–616**

Chronic disease, anemia of, **208t**, **211–212**, **212f**

Chronic eosinophilic leukemia, not otherwise specified, **102**, **950–951**, **951b**, **1015–1018**

clinical course of, **1018**

clinical features of, **1016**

definition of, **1015–1016**, **1016b**

differential diagnosis of, **1018**

epidemiology of, **1016**

etiology of, **1016**

genetics/molecular findings of, **1018**

immunophenotype/genetic testing of, **1002f**, **1017–1018**

morphology of, **1016–1017**, **1017f**

synonyms and related terms of, **1016**

Chronic lymphocytic leukemia (CLL), **149**

absence of primary aberrations in, **127–128**

bone marrow involvement in, **1131–1134**, **1136f–1137f**

versus classic Hodgkin lymphoma, **582**

copy number profiles for, **129f**

diffuse large B-cell lymphoma arising from, **449**, **451f**

FISH analysis of, **114f**

hairy cell leukemia and, **328**, **336t**

MALT lymphoma and, **397–398**, **398t**

paraimmunoblastic variant, diffuse large B-cell lymphoma and, **464t–465t**, **465**, **468f**

splenic marginal zone lymphoma and, **346t**

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), 77, **280–302**

accelerated, **287**

atypical/mixed, **286–287**, **288f–289f**

in blood, **284–285**, **284f**

in bone marrow, **285–286**, **285b**, **286f**

in central nervous system, **286**, **287f**

clinical course of, **297–298**

clinical features of, **282**

cytogenetic abnormalities in, **290**

definition of disease in, **280–281**, **281b**

deletion in

11q22-23, **292**

13q14, **290–291**

17p13, **292–293**

dermal infiltrates of, **286**

differential diagnosis of, **300–302**, **300f**, **301t–302t**, **302f–303f**

epidemiology of, **281**

fine-needle aspiration of, **17f**, **19–20**, **21f**

follicular lymphoma and, **380**, **381t**

genetic and molecular features of, **289–297**, **295t**

genomic profiling in, **294–296**

immunoglobulin structure in, **297**

immunophenotype of, **287–289**, **291t**, **292f–293f**

incidence of, **281**

in liver, **286**, **287f**

in lymph node, **282**, **283f**

lymphoplasmacytic lymphoma and Waldenström macroglobulinemia in, **325**

monoclonal B-cell lymphocytosis and, **281**

morphology of, **282–286**

nodal marginal zone lymphoma and, **421t**, **422**, **424f**

other cytogenetic abnormalities in, **293–294**

pearls and pitfalls in, **308**

postulated cell of origin and normal counterpart cell of, **297**

prognosis of, **297–298**

prognostic markers in, **297t**

with Reed-Sternberg cells, **287**, **290f**

somatic mutations in, **294–296**

in spleen, **282–284**, **284f**, **1212t**

stereotyped receptors in, **297**

transformation of, **298–300**, **298f–299f**

trisomy 12 in, **291–292**, **296f**

variants of, **280**, **281t**

morphologic, **286–287**, **288b**

Chronic lymphoproliferative disorders

of NK cells, *versus* aggressive NK-cell leukemia, **638**

post-therapy bone marrow evaluation in, **1177–1181**

cytogenetics and molecular studies in, **1180–1181**

immunophenotyping in, **1178–1180**, **1179f–1180f**

morphologic features of, **1177–1178**

Chronic lymphoproliferative neoplasms, B-cell, in chronic lymphocytic leukemia/small lymphocytic lymphoma, **285–286**, **301t–302t**

Chronic myeloid leukemia (CML), **98–101**, **920–929**

accelerated phase of, **925**, **925f–926f**, **926b**

atypical, **965–968**, **965b**

versus chronic myelomonocytic leukemia, **963**

clinical course of, **967**

clinical features of, **965**

cytogenetics/molecular findings of, **967**

definition of, **965**

differential diagnosis of, **967–968**

epidemiology of, **965**

etiology of, **965**

immunophenotype of, **967**

morphology of, **965–967**

prognosis and prognostic factors in, **968**

syndrome of abnormal chromatin clumping in, **966**, **967f**

BCR::*ABL1* positive

versus atypical chronic myeloid leukemia, **967–968**

versus chronic myelomonocytic leukemia, **963**, **964f**, **966f**

blast phase of, **925–926**, **927f**

chronic phase of, **920b**

clinical course of, **924–926**

clinical findings in, **921**

cytogenetics/molecular findings of, **923–924**, **924f**

definition of, **920**

differential diagnosis of, **928–929**, **928t**

associated with eosinophilia, **929**

atypical, **929**

chronic myelomonocytic leukemia and, **929**

chronic neutrophilic leukemia and, **929**

chronic phase of, **928**

myeloid or lymphoid blast phase of, **929**

reactive granulocytosis of, **928–929**

epidemiology of, **920**

in extramedullary tissue, **922–923**

immunophenotype of, **923**

morphologic findings of, **921–923**

post-therapy bone marrow evaluation in, **1171–1175**

cytogenetics and molecular studies in, **1174–1175**, **1176f**

immunophenotyping in, **1174**

morphologic features of, **1171–1174**, **1174f**

in spleen, **1218**, **1218f**

therapy, disease monitoring, and prognosis of, **926–928**, **928f**

Chronic myeloid neoplasms, **61–62**

Chronic myelomonocytic leukemia, **954–964**, **954b**

versus atypical chronic myeloid leukemia, **967**
chronic myeloid leukemia and, **929**
clinical course of, **962**
clinical features of, **955**
cytogenetics in, **961**
definition of, **954**
differential diagnosis of, **962–964**, **963b**

diagnosis of, **930**, **930b**
differential diagnosis of, **931–932**

epidemiology of, **930**

in extramedullary tissues, **931**

genetics of, **931**

morphologic findings of, **930–931**

Chronic osteomyelitis, of bone, **1194–1195**

Chronic renal failure, anemia of, **263**

Churg-Strauss syndrome, *versus* lymphomatoid granulomatosis, **598b**

Classic *BCR*::*ABL1*-negative myeloproliferative neoplasms, **932–933**, **932f**, **932t**

Classic Hodgkin lymphoma (CHL), **563–584.e11**

activated signaling pathways in, **576–577**

age and sex distribution of, **564**

versus anaplastic large-cell lymphoma, **580f**, **581–582**, **581t**

with B symptoms, **566**

cell of origin of, **577**

classification of, **563–564**, **564b**

clinical course and prognostic factors for, **577–578**

clinical features of, **566–567**

cytogenetics and molecular genetics of, **576**

definition of, **563–564**

versus diffuse large B-cell lymphoma, **579**, **580f**

diffuse large B-cell lymphoma and, **466**

epidemiology of, **564–565**

Epstein-Barr-negative, **566**

Epstein-Barr virus and, **564**

epidemiology of, **565**

infection of, functional consequences of, **565**

strains and variants of, **565**

versus Epstein-Barr virus-associated B-cell lymphoproliferations and lymphomas, **579–580**

other EBV-associated lymphoproliferative disorders, **580**

etiology of, **565–566**

extranodal manifestations of, **566**

extranodal sites of, diagnostic criteria for, **573**

familial, **564**

fine-needle aspiration of, **25–26**, **26f**

gene expression profiling for, **576–577**

genetics and molecular findings of, **575–577**

immunodeficiency disorders and, **564–565**

immunoglobulin and T-cell receptor genes in, **575–576**

immunophenotype of, **573–575**, **573t**, **574f**

incidence of, **564**

laboratory findings in, **566**

lymphocyte-depleted, **570t**, **571**

lymphocyte-rich, **570–571**, **570t**, **572f**

nodular variant of, **572f**, **575**

versus lymphomatoid granulomatosis, **598b**

mediastinal nodular sclerosis, **278**

mixed-cellularity, **570**, **570t**, **571f**

histiocyte-rich variant of, **570**, **571f**

morphology of, **567–573**

by histologic subtypes of, **567–573**, **570t**

Reed-Sternberg cells and variants in, **567**, **568f**

versus neoplasms of nonlymphoid origin, **582–583**

nodular lymphocyte-predominant, T-cell/histiocyte-rich large B-cell lymphoma and, **471–472**, **471t**

versus nodular lymphocyte-predominant Hodgkin lymphoma, **580–581**, **580f**, **581t**

nodular sclerosis, **475**, **476t**, **567–570**, **569f**, **570t**

versus anaplastic large cell lymphoma, **719**, **722f**, **733**

subclassification of, **567–570**

syncytial variant, **570**

versus other subtypes of non-Hodgkin lymphoma and composite lymphomas, **582**

pearls and pitfalls in, **583**, **583b**

peripheral T-cell lymphoma (PTCL), not otherwise specified, **805**

primary, primary cutaneous B-cell lymphomas and, **399**

primary cutaneous acral CD8-positive T-cell lymphoproliferative disorder, **801–803**

primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma, **792**

primary cutaneous γδ T-cell lymphoma, **794–796**

primary cutaneous T-follicular helper-cell lymphoma, **803**

rare subtypes of, **791–805.e4**

subcutaneous panniculitis-like T-cell lymphoma, **796–800**

CXCL12 (SDF-1), in B-cell differentiation, **136t**

CXCL13, in follicular helper T-cell, **709–711**, **711f**

CXCR4, in B-cell differentiation, **135–136**

Cycle threshold (C_T), **70**

Cyclic neutropenia, **234**, **234t**

Cyclin D genes, in multiple myeloma, **508–509**

Cyclin D1

in immunohistochemical diagnosis, **36**

in mantle cell lymphoma, **429f**, **432–433**, **434f**, **437–438**

oncogenic mechanisms of, **438**

overexpression of, **434**

Cyclin kinase inhibitor p27 (CDKN1B), and mantle cell lymphoma, **438**

Cyclophosphamide, for T-cell large granular lymphocytic leukemia, **652–653**

Cysts

bone, **1194**

mycosis fungoides with, **769**

splenic, **1226**

Cytochemistry

of acute myeloid leukemia, **890–891**

of blastic plasmacytoid dendritic cell neoplasm, **1028**

Cytogenetic abnormalities, in lymphoid neoplasms, classification of, **270**

Cytogenetic studies, for lymph node biopsy specimen, **12–13**

Cytokeratin-positive interstitial reticulin cell (CIRC) sarcoma, **1202**

Cytokine receptors, JAK kinases and, in myeloproliferative neoplasms, **917–918**

Cytologic imprint preparations, of lymph node biopsy specimen, **7f**

Cytologic preparations, of lymph node biopsy specimen, **4**

Cytomegalovirus infection

bone marrow findings in, **255**, **256f**

lymphadenopathies in, **182**, **182f**

posttransplant lymphoproliferative disorders and, **1106**

Cytopenia

chemotherapy-induced, myelodysplastic syndrome *versus*, **860**

myelodysplastic syndromes and, **841**

in T-cell large granular lymphocytic leukemia, **646**, **652**

Cytotoxic molecule-positive peripheral T-cell lymphoma, not otherwise specified, **693**, **694f**

Cytotoxic T-cell antigen-4

brain biopsies of, **1098f**

heterozygous germline mutations of, **1097–1098**, **1099f–1100f**

D

D rearrangement, myeloid/lymphoid neoplasms with eosinophilia with, **836t**

Daratumumab, for multiple myeloma, **525–526**

Darier's sign, **976**

DBA44, in hairy cell leukemia, **333**, **333t**

DCML deficiency, **873**

Decalcification, bone marrow biopsies, **33–35**

DEK::*NUP214,* in acute myeloid leukemia, **898**, **898f**, **898b**

Deletions, **110**

Dendritic cell(s)
neoplasms, **1048–1081**, **1049b–1050b**
plasmacytoid
immunohistochemical markers for, **1026t**
normal, **1029**, **1030f**, **1031b**
proliferations, **1034–1082.e17**
pearls and pitfalls in, **1081**, **1081b**

and reactive pseudotumoral lesions of the spleen, **1225–1226**

synonyms and related terms, **1077–1078**

Erdheim-Chester disease (ECD), **1060–1063**, **1062f**

association with other conditions of, **1063**

background of, **1060–1061**

clinical course of, **1063**

clinical features of, **1061**

definition of, **1060**
diagnostic criteria of, **1061**
differential diagnosis of, **1063**
epidemiology of, **1061**
genetics of, **1062–1063**
imaging findings of, **1061**
immunophenotype of, **1061**
molecular findings of, **1062–1063**
morphology of, **1061**
pathogenesis of, **1060–1061**
prognosis of, **1063**
synonyms and related terms, **1060**
Erythema infectiosum, **216**
Erythroderma
differential diagnosis of, **774**
in Sézary syndrome, **771–772**, **772f**
Erythrodermic allergic contact dermatitis, **774**
Erythrodermic psoriasis, **774**
Erythroid leukemia
flow cytometry in, **59**
pure, **908**, **909f**

Erythroid precursors, congenital disorders of, **226t**

Erythropoietin (EPO), bone marrow changes after, **1161**

Erythropoietin (EPO) receptor, **917–918**

Essential thrombocythemia, **933–938**

versus atypical chronic myeloid leukemia, **968**

clinical course of, **934–935**, **935b**

clinical features of, **933**

definition of, **933**

diagnosis of, **934b**

differential diagnosis of, **936–938**, **936b**

other myeloid neoplasms associated with, **936–938**, **936t**, **937f**

reactive thrombocytosis in, **936**

epidemiology of, **933**

in extramedullary tissues, **934**

genetics of, **934**

cytogenetics of, **934**

mutations in, **934**

morphology of, **933–934**

in spleen, **1220**

ETV6::*ABL1,* myeloid neoplasms with eosinophilia and, **1014–1015**

cell of origin of, postulated, **1015**

clinical course of, **1015**

clinical features of, **1014**

definition of, **1014**

differential diagnosis of, **1015**

epidemiology of, **1014**

etiology of, **1014**

genetics/molecular findings of, **1015**

immunophenotype of, **1014–1015**

morphology of, **1013t**, **1014**, **1015f**

normal counterpart of, **1015**

ETV6::*RUNX1* fusion, in B-cell acute lymphoblastic leukemia, **811**

Ewing's sarcoma, **1193**, **1193f**

Excess blasts, myelodysplastic syndrome with, **855–856**, **856t**

Exocytosis, **760–761**

Extracavitary primary effusion lymphoma, **606–607**

Extracutaneous mastocytoma, **997**

Extramedullary hematopoietic tumor, diffuse large B-cell lymphoma and, **464t–465t**, **468**, **468f**

Extranasal NK/T-cell lymphoma, **625–634**

versus blastic plasmacytoid dendritic cell neoplasm, **635t**

cell of origin, **633**
chromosomal abnormalities in, **633**
clinical course of, **633–634**
differential diagnosis of, **635t**, **636f–637f**
gene-expression profiles of, **633**
general features of, **625–626**, **626f–628f**
genetics and molecular findings in, **633**
grading of, **627–628**
versus herpes simplex infection, **634**
immunophenotype of, **628–633**, **631t**, **632f**
CD56-negative subset of, **632–633**
versus lymphomatoid granulomatosis, **634**, **635t**
morphology of, **625–627**
versus NK-cell enteropathy, **634**
versus primary cutaneous γδ T-cell lymphoma, **634**, **635t**
versus reactive lymphoid hyperplasia, **635t**, **636f**
site-specific features of, **626–627**, **629f–631f**
versus squamous cell carcinoma, **635t**
versus subcutaneous panniculitis-like T-cell lymphoma, **635t**
versus Wegener's granulomatosis, **634**, **635t**
Extranodal follicular lymphoma, **366**

Extranodal marginal zone lymphoma (EMZL)
of mucosa-associated lymphoid tissue, **79**
nodal marginal zone lymphoma and, **421**, **421t**
recurrent genetic abnormalities in, **80f**
Extranodal NK/T-cell lymphoma, **610**
bone marrow involvement in, **1146**, **1147f**
versus enteropathy-associated T-cell lymphoma, **752t**
versus lymphomatoid granulomatosis, **598b**
nasal type, **88**, **624–625**
clinical features of, **625**
definition of, **624**
diagnostic features of, **625b**
epidemiology of, **624**
etiology of, **624–625**
sites of, **1230t–1231t**
Extranodal peripheral T-cell lymphoma (PTCL), not otherwise specified, **693f**, **695–696**, **696f**
Exuberant reactive plasma cell proliferations, extraosseous plasmacytoma and, **533**
Eye, lymphoma of, **1232**

F

Fallopian tube, lymphoma of, **1253**

Familial hemophagocytic lymphohistiocytosis, **1221**

diagnostic criteria for, **1039**

Familial MDS/AML, **873**

Fanconi anemia, **246–248**, **246t**, **880–883**, **884f**

Fas-Fas ligand

system, in extranasal NK/T-cell lymphoma, **629–632**

in T-cell large granular lymphocytic leukemia, **652**

FAS gene mutations

in autoimmune lymphoproliferative syndrome, **1098–1099**

in Hodgkin lymphoma, **555**

Fascin, in lymphocyte-predominant cells, **548t–549t**, **551**

FASL gene mutations, in Hodgkin lymphoma, **555**

Felty syndrome, neutropenia associated with, **233**

Female genital tract, lymphoma of, **1253–1255**, **1254f–1255f**

Ferritin

for hemophagocytic lymphohistiocytosis, **1039**

serum, in iron deficiency, **207–208**

FGFR1 rearrangement, myeloid/lymphoid neoplasms with eosinophilia and, **835–837**, **1009–1011**

cell of origin of, postulated, **1009**

clinical course of, **1009**

definition of, **1009**

differential diagnosis of, **1009–1011**

epidemiology of, **1009**

etiology of, **1009**

genetics/molecular findings of, **1003b**, **1009**

immunophenotype of, **1009**

morphology of, **1006t**, **1009**, **1010f**, **1013t**

normal counterpart of, **1009**

synonyms and related terms of, **1009**

Fibrillary matrix, diffuse large B-cell lymphoma with, **456t**

Fibrin-associated diffuse large B-cell lymphoma, **594**

clinical features of, **594**

definition of, **594**

epidemiology of, **594**

pathology of, **586f**, **589f–591f**, **594**, **595f**

Fibrin ring granuloma, in Q fever, **254**, **255f**

Fibroblastic reticular cell tumor, Epstein-Barr virus-positive inflammatory, in spleen, **1222t**, **1225–1226**, **1226f**

Fibroma, nonossifying, **1194**

Fibrosis

in lymph node biopsy specimen, **4–5**

myelodysplastic syndrome with, **859**

Fibrous dysplasia, of bone, **1194**

Fifth disease, **216**

Fine-needle aspiration

of anaplastic large cell lymphoma, **27–28**, **28f**

of angioimmunoblastic T-cell lymphoma, **27**

of B-cell neoplasms, mature, **18–24**

of Burkitt lymphoma, **24**, **25f**

of chronic lymphocytic leukemia/small lymphocytic lymphoma, **17f**, **19–20**, 21f

of diffuse large B-cell lymphoma, not otherwise specified, **23–24**, **23f**

flow cytometry and, **45**

of follicular lymphoma, **21–22**

of Hodgkin lymphoma, **24–26**

classic, **25–26**, **26f**

nodular lymphocyte predominant, **26**

limitations of, **28–29**

of lymph nodes, **15–30.e5**

ancillary studies in, **16–18**

approach to, **16t**

non-neoplastic, **18**, **18f**

pearls and pitfalls in, **30b**

role of core needle biopsy in, **29**, **29f**

specimen collection and processing for, **16**, **17f**

of lymphoblastic leukemia/lymphoma, **28**, **28f**

of mantle cell lymphoma, **22–23**, **22f–23f**

of marginal zone lymphoma, **20–21**, **21f**

of molecular studies, **17–18**

of peripheral T-cell lymphoma, not otherwise specified, **26–27**, **27f**

of primary mediastinal (thymic) large B-cell lymphoma, **24**, **25f**

of T-cell neoplasms, mature, **26–28**

FISH, *See* **Fluorescence in situ hybridization**

Fixation

in bone marrow biopsies, **33–35**

in immunohistochemistry, **31**

of lymph node biopsy specimen, **8–10**, **9f–10f**, **9t**

Fixed lymph node tissue, microbiological evaluation of, **11–12**

FL, *See* **Follicular lymphoma**

Florid follicular hyperplasia with clonal B cells, **368**

Florid-reactive immunoblastic proliferation, diffuse large B-cell lymphoma and, **463**, **464t–465t**, **466f–467f**

Flow cytometry, **44–64.e7**

in acute leukemia, **57–61**

in acute lymphoblastic leukemia, **57**

in acute myeloid leukemia, **57–59**

antibody staining protocols for, **45**

in B-cell acute lymphoblastic leukemia/lymphoma, **59**, **60f**

chronic myeloid neoplasms, **61–62**

in adult T-cell leukemia/lymphoma, **663**, **664f**, **670–671**

disease associated with, **663**

geographic distribution of, **664f**

Human T-lymphotropic virus 2 (HTLV-2), **672**

Hyaline vascular Castleman disease, **165–166**, **166f**

differential diagnosis of, **165–166**

histology of, **165**, **166f**

immunophenotype of, **165**

stroma-rich variant of, **165**

Hybridization probe, **70**

Hydroa vacciniforme lymphoproliferative disorder, **618–620**

cell of origin of, **619**

classic, **618–619**, **619f**

clinical features of, **618–619**

definition of, **618**

diagnostic features of, **618t**

differential diagnosis of, **620**

epidemiology of, **618**

hydroa vacciniforme T cell lymphoma as, **620f**

immunophenotype and genetics of, **619**

morphology of, **619**

pathophysiology of, **618**

prognosis of, **619–620**

systemic, **619**, **620f**

Hydrolysis probes, **70–71**

Hydrops fetalis, **210–211**, **211f**

Hydroxyurea, bone marrow evaluation after, **1171–1173**

Hyper IgM type 1 syndrome, **1088–1090**, **1091f**

Hypercalcemia, in multiple myeloma, **511**

Hyperdiploidy

in acute lymphoblastic leukemia, **809–810**

high, **127**

in multiple myeloma, **508**

in POEMS syndrome, **540–541**

Hypereosinophilia, idiopathic, **1003b**, **1018–1019**, **1019b**, **1020f**

Hypereosinophilic syndrome (iHES), **1003b**, **1018–1019**, **1019b**, **1020f**

Hyperferritinemia, **1039**

Hyperplasia, paracortical, **171–172**

Hyperthyroidism, hematologic findings in, **264**

Hypodiploidy, in acute lymphoblastic leukemia, **810**

Hypogammaglobulinemia

in common variable immunodeficiency, **1090**

in X-linked lymphoproliferative disease, **1096**

Hypothyroidism, hematologic findings in, **264**

I

Iatrogenic immunodeficiency-associated lymphoproliferative disorders, **1104–1122**

classification of, **1104–1105**, **1105b**

definition of, **1104**

in nontransplant settings, **1119–1121**, **1120f**

pearls and pitfalls in, **1121**, **1121b**

posttransplant, **1105–1119**, **1105b–1106b**

bone marrow involvement in, **1108**

central nervous system involvement in, **1108**

classification of, **1105b**

clinical course of, **1117–1119**

clinical features of, **1108**

clonality studies of, **1116–1117**

differential diagnosis of, **1119**

epidemiology of, **1105–1106**

epigenetic studies of, **1117**

etiology of, **1106–1108**, **1107f**

gastrointestinal tract in, **1108**

genetics of, **1116–1117**

hepatosplenic T-cell lymphoma in, **1113–1114**, **1115f**

Hodgkin lymphoma, classic, **1114–1115**, **1116f**

immunophenotype of, **1115–1116**

infectious mononucleosis, **1108**, **1109f**

monomorphic, **1111–1114**

B-cell, **1111–1113**, **1113f–1114f**

NK-cell, **1113–1114**

T-cell, **1113–1114**, **1115f**

morphology of, **1105b–1106b**, **1108**

nondestructive, **1108–1110**, **1109f–1110f**

pearls and pitfalls in, **1121**, **1121b**

polymorphic, **1110–1111**, **1110f**, **1112f**

postulated normal counterparts of, **1117**

synonyms and related terms of, **1104**

ID2, in lymphocyte-predominant cells, **548t–549t**, **550**

IDH1/IDH2 mutation, **98**

Idiopathic cytopenia of undetermined significance (ICUS), **862**

Idiopathic dysplasia of undetermined significance (IDUS), **862**

Idiopathic hypereosinophilia (iHE), **1003b**, **1018–1019**, **1019b**, **1020f**

IFN, *See* **Type I interferons**

IG genes, in extranasal NK/T-cell lymphomas, **633**

IgD, *See* **Immunoglobulin D**

Igγ, in lymphocyte-predominant cells, **548t–549t**

IGH translocations, in multiple myeloma, **508**

Igκ, in lymphocyte-predominant cells, **548t–549t**

Imatinib, bone marrow morphology after, **1173**

Immature precursors, abnormal localization of, **1159–1160**, **1161f**

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX), **1097**

Immune-mediated thrombocytopenia, **238–239**

Immune system, homeostasis of, defects that affect, **1097–1100**

Immune thrombocytopenia
primary, **238–239**
secondary, **239**
Immune thrombocytopenic purpura, **238**
Immunoblasts
in B-cell lymphomas, **18**, **20f**
in diffuse large B-cell lymphoma, **450**, **453f**
Immunocytochemistry, of fine-needle lymphoid aspirates, **16**
Immunodeficiency
in ataxia telangiectasia, **1102–1103**
in autoimmune lymphoproliferative syndrome, **1098–1100**
in autosomal dominant immune dysregulation syndrome, **1097–1098**
Burkitt lymphoma associated with
clinical features and staging of, **485**
epidemiology of, **485**
genetics/molecular findings of, **488**
common variable, **1090–1092**, **1092f**
lymphomas associated with, diffuse large B-cell lymphoma and, **464t–465t**
PI3K-related, **1092–1097**, **1093f**, **1095f**

in agammaglobulinemia, **1092–1097**

in X-linked agammaglobulinemia, **1096**

X-linked inhibitor of apoptosis in, **1096**

in X-linked lymphoproliferative disease, **1096–1097**

primary, **1083–1103.e4**

classification of, **1086**

epidemiology of, **1086**

pathology of, **1083–1103.e4**

pearls and pitfalls, **1103b**

severe combined, **1086–1092**

in warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM), **1102**, **1102f**

in Wiskott-Aldrich syndrome, **1100–1102**

Immunodeficiency disorders, **278**

Immunofixation electrophoresis

in monoclonal gammopathy of undetermined significance, **528–529**, **532f**

in multiple myeloma, **510**, **511f**

Immunoglobulin A (IgA)

in lymphocyte-predominant cells, **548t–549t**

myeloma associated with, **515**, **517f**, **519f**

Immunoglobulin D (IgD)

in lymphocyte-predominant cells, **548t–549t**

in nodal marginal zone lymphoma, **414**

Immunoglobulin deposition disease, **534–539**

Immunoglobulin G (IgG), in lymphocyte-predominant cells, **548t–549t**

Immunoglobulin G4-related disease, **173–175**, **174f**

Immunoglobulin gene rearrangements, **66–69**

in nodular lymphocyte predominant B-cell lymphoma, **554**

Immunoglobulin genes

in Burkitt lymphoma, **488**

in classic Hodgkin lymphoma, **575–576**

Immunoglobulin heavy chain (IGH) genes

in benign lymphoid aggregates, **1129**

in follicular lymphoma, **352**

rearrangement of, in follicular helper T-cell, **709**

Immunoglobulin heavy chain variable region

in mantle cell lymphoma, **436**

in splenic marginal zone lymphoma, **344–345**

Immunoglobulin light chain

in benign lymphoid aggregates, **1132–1134**

in follicular lymphoma, **368–369**, **374**

Immunoglobulin M (IgM), in lymphocyte-predominant cells, **548t–549t**

Immunohistochemistry

antibodies, primary, **32–33**

antigens in, **31–32**

of hematopathologic interest, **35–37**

approach to using, **40**, **41f–42f**, **43t**

basic, **31–35**

of dendritic cell neoplasms, **37**

detection systems in, **33**

for hematopathology laboratory, **31–43.e3**

of high-grade B-cell lymphoma with *MYC* and *BCL2* rearrangements, **494**

of histiocytic, **37**

for immunostaining bone marrow biopsies, **33–35**

interpretive problems with, **33**, **34f**

of lymph node biopsy specimen, **12**, **12t**

of lymphoid malignancies, **35–36**, **35t**

of mast cell, **37**

of myeloid leukemias, myelodysplastic disorders, and other myeloproliferative diseases, **36–37**

pearls and pitfalls in, **40b**, **43t**

role of, **37–38**

in situ hybridization and, **38–40**

of tumor cell types, **37**

Immunophenotypic complexity, of immune system, in lymphoid neoplasms, classification of, **270**

Immunophenotyping, for follicular lymphoma, **382**

Immunoproliferative small intestinal disease (IPSID), **384–385**, **387**

Immunosuppressive therapy, lymphoproliferative disorders associated with

in nontransplant settings, **1118**

post-transplantation, **1105–1106**

In situ follicular neoplasia, **368**, **370f**

In situ hybridization (ISH), of lymph node biopsy specimen, **12**, **12t**

In situ mantle cell neoplasia, **435**, **436f**

Indeterminate dendritic cell histiocytosis (IDCH), **1059–1060**, **1060f**

Indolent clonal T-cell lymphoproliferative disorder, of gastrointestinal tract, **752t**, **755–756**, **756f**

Indolent mantle cell lymphoma, **442**

Indolent natural killer-cell lymphoproliferative disorder, of gastrointestinal tract, **752t**, **754**, **755f**

Indolent systemic mastocytosis, **982f**, **991–993**, **992f**

Infancy, neutropenia in, **230**

Infection

associated with hemolytic anemia, **218t**, **224**, **225f**

associated with neutropenia, **233**

associated with thrombocytopenia, **242**, **242f**

MALT lymphoma and, **386–388**

Infectious mononucleosis

classic Hodgkin lymphoma and, **565**

lymphadenopathy in, **179–182**, **181f**

posttransplant lymphoproliferative disorders, **1108**, **1109f**

Reed-Sternberg-like cells in, **582**

Infective dermatitis, **663–664**

Inflammation, anemia of, **211–212**

Inflammatory myofibroblastic tumors, *versus* anaplastic large cell lymphoma, **731t**, **733**

Inflammatory pseudotumor, **179**

of lung, *versus* lymphomatoid granulomatosis, **598b**

of lymph nodes, **1204–1205**, **1205f**

Infliximab, lymphoproliferative disorder associated with, **1120**

Innate immune response, differentiation of cells of, **157–158**

Innate immune response system, **136b**

Insertions, reciprocal, **110**

Interdigitating dendritic cell sarcoma, **1076–1077**, **1077f**

Interface dermatitides, **765**, **766f**

Interferon-α, bone marrow evaluation after, **1171–1173**

Interferon-producing cells, natural, **1029**

Interleukin-2, as growth factor, **1161**

Interleukin-3, as growth factor, **1161**

International Consensus Classification (ICC), **273–277**

of myeloid, lymphoid, and histiocytic neoplasms, **1258t–1260t**

of myeloid neoplasms, **833–838**, **835b**, **836t**

International Prognostic Index (IPI), **462**

International System for Human Cytogenetic Nomenclature (ISCN), **112**

Interstitial pneumonia, *versus* lymphomatoid granulomatosis, **598b**

Intestinal diffuse large B-cell lymphoma, **1247–1248**, **1247f**

Intestinal T-cell lymphoma

monomorphic epitheliotropic, **749–753**

clinical course of, **751–752**

clinical presentation of, **750**

definition of, **749**

epidemiology of, **749**

etiology of, **749–750**

histopathology, **750**, **751f**

immunohistochemistry of, **750–751**, **751f–752f**, **752t**

molecular analysis and genetic abnormalities of, **752t**, **753**

pathogenesis of, **752–753**

pathology of, **750**

postulated cell of origin of, **752–753**

synonyms and related terms of, **749**

not otherwise specified, **752t**, **753–754**

Intraocular lymphoma, **1232**

Intraoperative consultation, of lymph node biopsy specimen, **5**

Intravascular large B-cell lymphoma, **409**, **409f**, **464t–465t**, **476–479**

bone marrow involvement in, **1142–1144**, **1144f**

cell of origin of, **478**

clinical course of, **478**

clinical features of, **476–477**

definition of, **476**

differential diagnosis of, **478–479**

epidemiology of, **476**

etiology of, **476**

genetics of, **477–478**

immunophenotype of, **477**, **479f**

morphology of, **476t**, **477f–478f**, **477**

Invasive breast carcinoma, **1189**, **1190f**

Inversions, reciprocal, **110**

IRF4 translocations, in B lymphoblastic leukemia/lymphoma, **130**

Iron-deficiency anemia, **207–208**, **208f**

immunohistochemical panels for, **35t**

infarction of, in diffuse large B-cell lymphoma, **450–451**, **456f**

Langerhans cell histiocytosis in, **1056**, **1057f**

lymphoplasmacytic lymphoma and Waldenström macroglobulinemia in, **315**, **318f**

MALT lymphoma in, **393**, **397f**

mastocytosis in, **985–986**, **986f**

mesenchymal proliferations in, **1203–1208**

bone marrow hematopoietic elements and tumors involving, **1207–1208**, **1208f–1209f**

inflammatory pseudotumor of, **1204–1205**, **1205f**

Kaposi sarcoma, **1205**, **1206f**

metastatic sarcomas of other types, **1206–1207**, **1207f**

mixed smooth muscle-vascular proliferations, **1203–1204**, **1204f**

vascular transformation of lymph node sinuses and lymphatic proliferations, **1203**, **1203f**

vascular tumors of, **1205–1206**, **1206f–1207f**

metastatic tumors of, **1195–1201**

characteristic biological patterns of, **1197**

diagnosis of, immunohistochemistry in, role of, **1198–1200**, **1199f**, **1199t–1200t**

histologic features of, **1189t**, **1195–1197**, **1196f–1198f**

nonlymphoid tumors with prominent reactive lymphoid components, **1200–1201**, **1200f–1201f**

monoclonal B-cell lymphocytosis in, **305**

nodal marginal zone lymphoma in, **414–416**, **414f**

paracortex, **143f**

splenic marginal zone lymphoma in, **339**, **341f**

in systemic EBV-positive T-cell lymphoma of childhood, **621**, **622f–623f**

in T-cell prolymphocytic leukemia, **655**, **658f**

vasculature and conduit system, **144**

Lymph node biopsy specimen, **1–14.e2**

ancillary studies of, **11t**, **13t**

assessing and prioritizing fresh tissue, **3–4**, **5f**

cytologic preparations of, **5–8**, **7f**

fixation of, **8–10**, **9f–10f**, **9t**

frozen sections of, **5**

gross examination of, **4–5**, **6f**

gross processing of, **4–11**

histotechnologist contribution in, **10**

pearls and pitfalls in, **13b**

reporting of, **13**

sectioning of, **8**, **8f**

selection of, **4f**

stains for, **11–13**

Lymph node morphology

in diffuse large B-cell lymphoma, **449**, **449f–457f**

in intravascular large B-cell lymphoma, **477**, **477f–478f**

in primary mediastinal (thymic) large B-cell lymphoma, **472–476**

in T-cell/histiocyte-rich large B-cell lymphoma, **469**, **470f**

Lymphadenitis

dermatopathic, **171–172**, **171f**

granulomatous, **172–173**

herpes simplex, **182**, **183f**

histiocyte-rich, **731t**, **733**

Kikuchi, **176–179**

diffuse large B-cell lymphoma and, **463–465**, **464t–465t**

leishmanial, **176**

luetic, **164–165**, **164f**

lupus, **178–179**

toxoplasmic, **175–176**, **177f**

Lymphadenopathic mastocytosis with eosinophilia, **985–986**, **995**

Lymphadenopathy

in autoimmune disorders, **162–164**, **163f**

autosomal dominant immune dysregulation syndrome and, **1097**

in bacillary angiomatosis, **179**, **180f**

in cytomegalovirus infection, **182**, **182f**

dilantin-associated, **183f**

drug-associated, **183**

HIV-associated, *versus* hyaline vascular Castleman disease, **165–166**

in infectious mononucleosis, **179–182**, **181f**

in Kawasaki disease, **179**

in LCH, **1052**

in mantle zone hyperplasia, **168**, **168f**

in primary cutaneous CD30-positive T-cell lymphoproliferative disorders, **779**, **780f**

reactive, **159–184.e7**, **160b**

versus classic Hodgkin lymphoma, **582**

with diffuse pattern, **179–183**

with follicular and nodular patterns, **159–168**

with interfollicular or mixed patterns, **171–179**

pearls and pitfalls in, **183b**

with predominantly sinus pattern, **168–171**

in syphilis, **164**, **164f**

Lymphangiogram, histiocytic expansion with, **168–169**, **169f**

Lymphoblastic leukemia

cytomorphology of, **28**, **28f**

fine-needle aspiration of, **28**, **28f**

Lymphoblastic lymphoma

cytomorphology of, **28**

differential diagnosis of, **815t**

fine-needle aspiration of, **28**, **28f**

Lymphoblasts, in post-therapy bone marrow evaluation, **1168–1169**

Lymphocyte-predominant cells, **547**

antigen expression of, **548t–549t**

cell cycle proteins in, **548t–549t**, **551**

immunophenotype of, **547–553**

lymphocyte-signaling molecules in, **547–550**, **547f**, **549f**

signaling intermediates in, **548t–549t**, **550**

structural proteins and adhesion molecules in, **548t–549t**, **551**

transcription factors and regulators in, **548t–549t**, **550**

tumor suppressors and apoptosis-related proteins in, **548t–549t**, **551**

Lymphocyte-signaling molecules, in nodular lymphocyte predominant B-cell lymphoma, **547–550**, **549f**

Lymphocytic lymphoma (LPL), splenic marginal zone lymphoma and, **346t**

Lymphocytic mastopathy, **1246**

Lymphocytosis

B-cell

monoclonal, **281**, **302–305**

persistent polyclonal, **251**, **252b**

polyclonal, **251**, **252f**

in CLL/SLL, **280–281**

in Epstein-Barr virus, **255**, **257f**

polyclonal, benign, **300**

reactive, **251**, **251f–252f**, **644**

Lymphoepithelial sialadenitis, **386f**, **388–389**, **390f**, **1238**

Lymphoepithelioid variant, of peripheral T-cell lymphoma, **688f**, **692**, **699**, **699t**

Lymphoepithelium

in MALT lymphoma, **389**, **391f**

of parotid gland, **397f**

in Peyer's patches, **384f**

in reactive *versus* neoplastic MALT, **396**, **397f**

Lymphoglandular bodies, in diffuse large B-cell lymphoma, not otherwise specified, **18f**, **23**

Lymphohistiocytic anaplastic large cell lymphoma, **718**, **720f**, **731t**, **733**

Lymphohistiocytosis

hemophagocytic, **170–171**, **171f**, **1034–1045**, **1041f–1043f**

clinical course of, **1041–1044**, **1044t**

clinical features of, **1038–1039**, **1039b**

definition of, **1034**

differential diagnosis of, **1044–1045**

epidemiology of, **1034–1035**
Epstein-Barr virus-associated, **611–613**
cells of origin of, **613**
clinical course and prognostic factors in, **613**
clinical features of, **612**
definition of, **611**
diagnostic features of, **611b**
differential diagnosis of, **613**
epidemiology of, **611**
immunophenotype and genetics of, **612–613**
morphology of, **612**, **612f**
pathophysiology of, **611–612**
primary, **611**
secondary, **611**
etiology and pathogenesis of, **1035–1038**
immunophenotype of, **1040–1041**
morphology of, **1039–1040**
primary or genetic, **1035–1037**, **1036t**
prognosis of, **1041–1044**, **1044t**
secondary or reactive, **1037–1038**
Lymphoid aggregates, benign, in bone marrow, **1126–1130**

flow cytometric immunophenotyping of, **1128–1129**, **1133f**

immunohistochemistry of, **1127–1128**, **1129f–1131f**

molecular diagnostic studies of, **1129–1130**

morphology of, **1126**, **1127f–1128f**, **1127t**

Lymphoid-appearing myeloma, **521**

Lymphoid follicles (Malpighian corpuscles), splenic, **1211**, **1211t**, **1212f**

Lymphoid hyperplasia

cutaneous, primary cutaneous marginal zone lymphoma and, **402**, **407t**

reactive

versus extranasal NK/T-cell lymphoma, **635t**

fine-needle aspiration of, **18**, **18f**

versus peripheral T-cell lymphoma, not otherwise specified, **698–699**

of spleen, **1213–1214**

T-cell/histiocyte-rich large B-cell lymphoma and, **471**

of spleen, **1213–1214**, **1213f**

Lymphoid malignancies, immunohistochemistry of, **35–36**, **35t**

Lymphoid/myeloid neoplasms, with eosinophilia, **835–837**, **836t**, **1001–1015**

ETV6-ABL1 and, **1014–1015**

cell of origin of, postulated, **1015**
clinical course of, **1015**
clinical features of, **1014**
definition of, **1014**
differential diagnosis of, **1015**
epidemiology of, **1014**
etiology of, **1014**
genetics/molecular findings of, **1015**
immunophenotype of, **1014–1015**
morphology of, **1013t**, **1014**, **1015f**
normal counterpart of, **1015**
FGFR1 rearrangement, **1009–1011**
cell of origin of, postulated, **1009**
clinical course of, **1009**
definition of, **1009**
differential diagnosis of, **1009–1011**
epidemiology of, **1009**
etiology of, **1009**
genetics/molecular findings of, **1003b**, **1009**
immunophenotype of, **1009**
morphology of, **1006t**, **1009**, **1010f**, **1013t**

normal counterpart of, **1009**

synonyms and related terms of, **1009**

FLT3 rearrangement, **1012–1014**, **1013t**, **1014f**

JAK2 rearrangement, **1011–1012**

cell of origin of, postulated, **1011**

clinical course of, **1011–1012**

clinical features of, **1011**

definition of, **1011**

differential diagnosis of, **1012**

epidemiology of, **1011**

etiology of, **1011**

genetics/molecular findings of, **1003b**, **1011**

immunophenotype of, **1011**

morphology of, **1011**, **1012f**

normal counterpart of, **1011**

synonyms and related terms of, **1011**

variants of, **1012**

PDGFRA rearrangement, **1002–1005**

cell of origin of, postulated, **1004**

clinical course of, **1004–1005**

clinical features of, **1003**

definition of, **1002**

differential diagnosis of, **1005**, **1005f**, **1006t**, **1013t**

epidemiology of, **1003**

etiology of, **1003**

genetic/molecular findings of, **1003–1004**, **1003b**, **1005f**

genetics of, **1003**, **1003b**

immunophenotype of, **1003**

morphology of, **1003**, **1004f–1005f**

normal counterpart of, **1004**

synonyms and related terms of, **1003**

PDGFRB rearrangement, **1005–1009**

cell of origin of, postulated, **1008**

clinical course of, **1008**

clinical features of, **1006**

definition of, **1005–1006**

differential diagnosis of, **1006t**, **1008–1009**, **1013t**

epidemiology of, **1006**

etiology of, **1006**

genetics/molecular findings of, **1003b**, **1008**

immunophenotype of, **1008**

morphology of, **1006–1008**, **1007f**

normal counterpart of, **1008**

synonyms and related terms of, **1006**

Lymphoid neoplasms, **77–91**

aspirates of, **18–28**, **19t**

associated with Down syndrome, **886–887**

classification of, **267–279.e3**

historical background on, **269–273**, **270f**, **271t–272t**, **272f**, **274t–277t**

ICC and WHO 5th ed. proposals, **273–278**

pearls and pitfalls in, **279b**

Revised European American Lymphoma (REAL), **269**

WHO 2008, **273–277**

copy number alterations with prognostic significance in, **131–132**

with germline *CEBPA* mutation, **870–871**

with germline *DDX41* mutation, **871–872**, **871f**

with germline *ETV6* mutation, **873**, **876f**

with germline *RUNX1* mutation, **872–873**, **874f–875f**

with germline *TP53* mutation, **872**

International Consensus Classification of, **1258t–1260t**

leukemic, atypical, mantle cell lymphoma and, **443**

mature, **77–89**

precursor, **89–91**
classification of, **806**
in spleen, **1216**
Lymphoid proliferations, determination of clonality in, **69**
Lymphoid sheaths, periarteriolar, **1211**, **1211t**
Lymphoid tissues
in bone marrow, **135–136**, **136t**
in lymph nodes, **138**, **138f–139f**
normal, **135–147**
pearls and pitfalls in, **158b**
primary (central), **135–138**
secondary (peripheral), **138–147**, **140f–141f**
in thymus, **136–138**
Lymphoma
of adrenal gland, **1249**
anaplastic large cell, **1152–1153**, **1153f**
B-cell, **1131–1146**
diffuse large, **1141–1142**, **1143f–1144f**
high-grade, **1145**
intravascular large, **1142–1144**, **1144f**
B-lymphoblastic, **1145–1146**

versus benign lymphoid aggregates, **1126–1130**
flow cytometric immunophenotyping of, **1128–1129**, **1133f**
immunohistochemistry of, **1127–1128**, **1129f–1131f**
molecular diagnostic studies of, **1129–1130**
morphology of, **1126**, **1127f–1128f**, **1127t**
of bladder, **1250–1251**
of bone, **1255–1256**, **1256f**
in bone marrow
versus benign lymphoid aggregates, **1126–1130**
flow cytometric immunophenotyping of, **1128–1129**, **1133f**

Multiple organ systems, hematologic neoplasms with germline predisposition, with constitutional disorder affecting, **870–872**

Multisystem LCH (MS-LCH), **1052**

MUM-1, in lymphocyte-predominant cells, **548t–549t**, **550**

Mummified cells, **567**, **568f**

Mutational analysis, in myeloid neoplasms, **833**

Mutations
in acute myeloid leukemia, **95–97**
point, in normal individuals, **106–107**
MYC protein expression, in diffuse large B-cell lymphoma, **452**, **462**
MYC rearrangement
in diffuse large B-cell lymphoma, **454**, **463**
in follicular lymphoma, **375**
in high-grade B-cell lymphoma, **490t**, **495**
historical perspective on, **482–483**
MYC translocation
in Burkitt lymphoma, **488**, **489f**
with Epstein-Barr virus infection, **484**
specificity to, **490–491**
in plasmablastic lymphoma, **501**
Mycobacterial spindle cell pseudotumor, **168**
Mycobacterium avium-intracellulare infection, bone marrow findings in, **253–254**, **254f**
Mycobacterium tuberculosis infection, bone marrow findings in, **253–254**, **254f**
Mycoplasma pneumonia, red cell abnormalities in, **253**
Mycosis fungoides, **85t–87t**, **89**, **758–771**, **759b**

versus adult T-cell leukemia/lymphoma, **672**, **672t**
atrophic or poikilodermatous patch stage of, **767–768**
bone marrow involvement in, **1148**, **1150f**
bullous, **769**
cell of origin in, **765**
in children, **766–767**
clinical course of, **765**
clinical features of, **759–760**, **760f–761f**
with cysts and comedones, **769**
definition of, **758**, **759b**
versus dermatopathic lymphadenitis, **172**
differential diagnosis of, **765–768**, **765f–767f**
epidemiology of, **758–759**
etiology of, **759**
folliculotropic, **768–769**, **769f**
genotypic features of, **765**
grading of, **763–764**
granulomatous, **771**, **771f**
granulomatous slack skin and, **771**, **771f–772f**
histopathology, **760–763**
in patch stage, **760**, **761f–762f**, **762b**

in plaque stage, **761–762**, **763f–764f**

in tumor stage, **762–763**, **763f–764f**

immunophenotype of, **764**

Ketron-Goodman variant of, **770**

lymphomatoid papulosis and, **777f**, **787**, **787t**

pagetoid reticulosis of, **769–770**, **770f**

pearls and pitfalls in, **774**, **774b**

solitary, **770–771**

in spleen, **1217**

syringotropic, **769**, **770f**

variants of, **768–771**

Mycosis fungoides-Sézary syndrome (MF-SS), *versus* T-cell prolymphocytic leukemia, **661t–662t**

Myeloablative therapy, bone marrow changes after, **1159b**, **1160f**

Myeloblasts, in acute myeloid leukemia, **890**

Myelodysplasia-related gene mutations, **97–98**

Myelodysplastic disorders, in immunohistochemistry, **36–37**

Myelodysplastic/myeloproliferative neoplasms, **953–974.e4**, **837**

characteristics of, **836t**

introduction of, **953–954**

with isolated isochromosome, **971–972**, **972b**

clinical findings of, **971**

definition of, **971**

differential diagnosis of, **972**

epidemiology of, **971**

etiology of, **971**

genetics of, **972**

morphology of, **972**

prognosis of, **972**

not otherwise specified, **971**, **971b**

pearls and pitfalls in, **974**, **974b**

with ring sideroblasts and thrombocytosis, not otherwise specified, **970**, **971b**

differential diagnosis, **970**

versus myeloproliferative neoplasm with ring sideroblasts, *SF3B1* mutation negative, **970**

with *SF3B1* mutation and thrombocytosis, **968–970**, **968b**

clinical findings of, **968**

cytogenetics and genetics of, **970**

differential diagnosis of, **970**

epidemiology of, **968**

etiology of, **968**

immunophenotype in, **970**

morphology of, **968–970**

prognosis and prognostic factors of, **970**

WHO classification of, **953–954**, **954b**

Myelodysplastic syndrome, **840–866.e9**, **102–105**, **119t–120t**, **120–121**, **837**, **866b**, **1022**

versus acute myeloid leukemia, **851–852**, **852f**

additional considerations in, **859–860**

associations between cytogenetic findings and clinical outcome of MDS patients, **121**

versus atypical chronic myeloid leukemia, **968**

blood counts in, **841**, **842t**

characteristics of, **836t**

in children, **857–858**, **857t**

versus chronic myelomonocytic leukemia, **964**

classification of, **850–860**

clinical features of, **840–841**

versus clonal hematopoiesis, **850–851**, **850b**, **851t**

common recurrent unbalanced chromosome aberrations in, **121t**

cytogenetic abnormalities in, **103t**

cytogenetic scoring system for, **849t**

with del(5q), **852–853**, **853t**

diagnosis of, **849–850**, **850b**

differential diagnosis, **860–865**

- acute myeloid leukemia with recurrent genetic abnormalities, **863–864**
- aplastic anemia, **862**
- arsenic exposure, **861**
- chemotherapy-induced dysplasia and cytopenias, **860**
- chronic viral infections, **861–862**
- clonal cytopenia of undetermined significance (CCUS), **863**
- clonal hematopoiesis, **860**
- clonal hematopoiesis of indeterminate potential (CHIP), **863**
- congenital dyserythropoietic anemias, **861**
- copper deficiency, **861**
- germline predisposition conditions, **862–863**
- idiopathic cytopenia of undetermined significance (ICUS), **862**
- idiopathic dysplasia of undetermined significance (IDUS), **862**
- large granular lymphocytic leukemia, **864–865**
- marrow dysplasia in HIV infection, **861**

marrow recovery after acute marrow injury or stem cell transplantation, **861**

megaloblastic anemia, **860**

non-myelodysplastic syndrome sideroblastic anemias, **861**

paroxysmal nocturnal hemoglobinuria, **862**

pathogenesis of, **865**

post-acute myeloid leukemia dysplasia, **860**

primary myelofibrosis, **864**

VEXAS syndrome, **863**

zinc toxicity, **861**

disease heterogeneity within, **852**

erythroid-predominant, **859–860**

etiology of, **865**

with excess blasts, **855–856**, **856t**

with fibrosis, **859**

flow cytometry in, **61–62**, **61f**, **843–845**, **846t**

general cytogenetic features of, **120**

genetic abnormalities in, **845–849**, **847t–848t**

germline predisposition, **858**

hypoplastic, **859**

incidence of, **840**

international consensus classification of, **852–857**, **853t**

laboratory features of, **841–849**

microscopic features of, **841–843**, **843t**, **844f–846f**

molecular basis of, **104f**

with mutated *SF3B1*, **853–854**, **854t**

with mutated *TP53*, **855**, **856t**

not otherwise specified (NOS), **854–855**, **855t**

peripheral blood count in, **841–843**, **843t**

post-therapy bone marrow evaluation in, **1163–1170**

cytogenetics and molecular studies in, **1166–1168**, **1168f**, **1172f**, **1173t**

immunophenotyping in, **1165–1166**, **1166f**

morphologic features of, **1164–1165**, **1165f–1166f**

prognostic scoring systems, **858–859**

recurrent mutations in, **104t**

with *SF3B1* mutation, *versus* myelodysplastic/myeloproliferative neoplasm with *SF3B1* mutation and thrombocytosis, **970**

synonyms and related terms, **840**

therapy-related, **1185f**

therapy-relatedness, **858**

WHO classification of, **852–857**, **853t**

Myelodysplastic syndrome/acute myeloid leukemia (MDS/AML), **856–857**, **857t**

Myelofibrosis

acute panmyelosis with, **909–910**, **910f**

autoimmune, **261–262**, **262f**

primary, **938–944**

versus atypical chronic myeloid leukemia, **968**

definition of, **938**

early/prefibrotic

clinical course of, **939**

clinical features of, **938–939**

differential diagnosis of, **936t**

early/prefibrotic, **938–939**, **938b**

epidemiology of, **938**

in extramedullary tissues, **939**

genetic findings of, **939**

morphology of, **939**

myelodysplastic syndrome *versus*, **864**

overt, **939–944**, **941b**

clinical course of, **943–944**

clinical features of, **941**

differential diagnosis of, **944**, **944t**, **945f–946f**, **947t**

epidemiology of, **941**

in extramedullary tissues, **942–943**, **943f**

genetics of, **943**

morphology of, **941–943**

in spleen, **1219–1220**, **1219f**, **1219t**

Myeloid differentiation primary response 88 gene *(MYD88),* mutation of, in lymphoplasmacytic lymphoma and Waldenström macroglobulinemia, **320f**, **321**

Myeloid leukemia

acute, *versus* chronic myelomonocytic leukemia, **963**

in immunohistochemistry, **36–37**

Myeloid lineage, acute leukemia, **823–824**, **823t–824t**

Myeloid/lymphoid neoplasms, with eosinophilia, **835–837**, **836t**, **1001–1015**

ETV6-ABL1 and, **1014–1015**

cell of origin of, postulated, **1015**

immunophenotype of, **416–417**, **418f**

lymphoplasmacytic lymphoma and, **421–422**, **421f**

MALT type of, **413f**, **414–416**

molecular findings in, **417**

monocytoid B-cell hyperplasia and, **422**

morphology of, **413–416**

pearls and pitfalls in, **425**, **425b**

pediatric-type, **419–421**, **419f**

polymorphic type of, **417**, **419f**

postulated cell of origin in, **417–419**

prognostic factors of, **419**

splenic marginal zone lymphoma and, **423**, **425f**

splenic type of, **414–416**, **415f**

Nodal NK/T-cell lymphoma, Epstein-Barr virus-positive, **640–642**

clinical features of, **640**

definition of, **640**

diagnostic features of, **640b**

differential diagnosis of, **641–642**

epidemiology of, **640**

immunophenotype and genetics of, **641**

morphology of, **640–641**, **641f**

pathophysiology of, **640**

prognosis for, **641**

Nodular lymphocyte predominant B-cell lymphoma (NLPBCL), **278**

Nodular sclerosis classic Hodgkin lymphoma, **564**, **567–570**, **569f**, **570t**

Nodularity, in lymph node biopsy specimen, **4–5**

Non-hematolymphoid malignancies, diffuse large B-cell lymphoma and, **464t–465t**, **468**

Non-hematopoietic neoplasms, of bone marrow, **1188–1209.e4**, **1209b**

Non-Hodgkin lymphoma, **128t**

versus nodular lymphocyte predominant B-cell lymphoma, **559**

in spleen, **1215–1216**

Non-myelodysplastic syndrome sideroblastic anemias, **861**

Non-neoplastic histiocytic disorders, **1034–1048**

Gaucher disease, **1045–1046**, **1046f**

hemophagocytic lymphohistiocytosis, **1034–1045**, **1041f–1043f**

clinical course of, **1041–1044**, **1044t**

clinical features of, **1038–1039**, **1039b**

definition of, **1034**

differential diagnosis of, **1044–1045**

epidemiology of, **1034–1035**

etiology and pathogenesis of, **1035–1038**

immunophenotype of, **1040–1041**

morphology of, **1039–1040**

primary or genetic, **1035–1037**, **1036t**

prognosis of, **1041–1044**, **1044t**

secondary or reactive, **1037–1038**

Niemann-Pick disease, **1046–1048**, **1047f**

Tangier disease, **1048**, **1048f**

Non-T-cell activation linker (NTAL), in lymphocyte-predominant cells, **548t–549t**, **550**

Nondestructive posttransplant lymphoproliferative disorders, **1108–1110**, **1109f–1110f**

Nonlymphoid malignancies, mimicking lymphoma, bone marrow involvement in, **1155–1156**

Nonlymphoid tumors

LK-positive, **733**, **734f**

with prominent reactive lymphoid components, of lymph nodes, **1200–1201**, **1200f–1201f**

Noonan syndrome, juvenile myelomonocytic leukemia associated with, **886**

Noonan-syndrome-like disorders (CBL-Syndrome), juvenile myelomonocytic leukemia associated with, **886**

Normochromic normocytic anemia, **211–215**

high output, **217–224**

underproduction, **215–217**

NOTCH1, in T-cell lymphoblastic leukemia/lymphoma, **818**

NPM-ALK protein, **721**

NPM1 gene, **36**

NPM1 mutations, **96–97**

acute myeloid leukemia with, **894f**, **902–903**

in myelodysplastic/myeloproliferative neoplasms, **962**

Nuclear factor-κB, in lymphocyte-predominant cells, **550**

Nuclear factor-κB pathway, activation of, **457**

Nuclear factor of activated T cells (NFAT), in lymphocyte-predominant cells, **550**

Nucleic acid isolation, **65–66**

O

Oct-1, in lymphocyte-predominant cells, **548t–549t**, **550**

Oct-2, in lymphocyte-predominant cells, **548t–549t**, **550**

Ocular adnexal lymphoma, **1233–1235**

Ocular adnexal MALT lymphoma, **387**

Ocular lymphoma, **1232**

OKT3, posttransplant lymphoproliferative disorders associated with, **1106**

Omenn syndrome, **1088**, **1088f–1089f**

Oncogene abnormalities, in follicular lymphoma, **374t**

Optical genome mapping (OGM), **75–76**

Oral cavity, lymphoma of, **1238–1239**, **1238f**

Osmotic fragility studies, in hereditary spherocytosis, **220**

Osteitis fibrosa, **1195**, **1195f**

Osteochondroma, **1194**

Osteoclastoma, **1194**

Osteomyelitis, chronic, **1194–1195**

Osteoporosis, **1195**

Osteosarcoma, **1193–1194**

Ovalocytosis, Southeast Asian, **220**

Ovarian lymphoma, **1253**

Overt primary myelofibrosis, **939–944**, **941b**

clinical course of, **943–944**

clinical features of, **941**

differential diagnosis of, **944**, **944t**, **945f–946f**, **947t**

epidemiology of, **941**

in extramedullary tissues, **942–943**, **943f**

genetics of, **943**

morphology of, **941–943**

P

p27, in mantle cell lymphoma, **434**, **438**

immunoreactivity for, in diffuse large B-cell lymphoma, **454–455**

in lymphocyte-predominant cells, **548t–549t**, **551**

in T-cell prolymphocytic leukemia, **661**

p65, in lymphocyte-predominant cells, **548t–549t**, **550**

Pagetoid appearance, primary cutaneous T-cell lymphomas and, **792–793**, **793f**

Pagetoid reticulosis, **769–770**, **770f**

Paget's disease, of bone, **1194**

Pan-T-cell antigen(s), **688**

Pancreas, lymphoma of, **1249**

Pancreatobiliary tract, lymphoma of, **1248–1249**

Papanicolaou stain

of fine-needle aspiration, **16**

for lymph node biopsy specimen, **7–8**

Paracortex, **142–144**, **143f**

Paracortical hyperplasia, **171–172**

fine-needle aspiration of, **18**

versus follicular helper T-cell, **713**, **714t**

Paracortical lymphoid nodules, **171–172**

Paranasal sinuses, lymphoma of, **1236–1237**

Parapsoriasis, **759**

Parasitic infection, in bone marrow, **255**

Paroxysmal nocturnal hemoglobinuria, **245**, **246t**, **247f**

myelodysplastic syndrome *versus*, **862**

Parvovirus B19

bone marrow findings in, **256**

in pure red cell aplasia, **216**, **216f**

Patches, in mycosis fungoides, **759**, **760f–762f**, **762b**

Pautrier's microabscesses, in mycosis fungoides, **761–762**, **763f**, **765–766**

PCDLBCL, LT, *See* **Primary cutaneous diffuse large B-cell lymphoma, leg type**

PCFCL, *See* **Primary cutaneous follicle center lymphoma**

PCMZLPD, *See* **Primary cutaneous marginal zone lymphoproliferative disorder**

PCNA, in lymphocyte-predominant cells, **548t–549t**

PDGFRA, in myeloproliferative neoplasms, unclassifiable, **951**

PDGFRA rearrangement, myeloid/lymphoid neoplasms with eosinophilia and, **835–837**, **1002–1005**

- cell of origin of, postulated, **1004**
- clinical course of, **1004–1005**
- clinical features of, **1003**

Southern blot analysis, for classic Hodgkin lymphoma, **565**

Southern blotting hybridization analysis, **65**

SOX11, **434–435**

- oncogenic mechanisms of, **438**

Spectral karyotyping (SKY) analysis, **115**, **117f**

Spherocytosis, hereditary, **218–220**, **219f**, **219t**

Spindle-cell morphology, in diffuse large B-cell lymphoma, **456t**

Spleen, **144**, **145f**

- angiosarcoma of, **1222t**, **1223–1224**, **1223f**
- autoimmune lymphoproliferative syndrome in, **1214**, **1215f**
- B-cell lymphoma in, **1212t**, **1216–1217**, **1216f–1217f**
- B-chronic lymphoproliferative neoplasms in, **301t**
- benign lesions of, that simulate hematopoietic malignancies, **1213b**
- Castleman disease in, **1214**

chronic lymphocytic leukemia/small lymphocytic lymphoma in, **282–284**, **284f**

chronic myeloid leukemia in, **1218**, **1218f**

chronic myelomonocytic leukemia in, **1219–1220**

classic Hodgkin lymphoma in, **566**

diffuse large B-cell lymphoma in, **1216**, **1216f–1217f**

enlargement, diffuse, **1211–1213**

Epstein-Barr virus-positive inflammatory follicular dendritic cell tumor of, **1222t**, **1225–1226**, **1226f**

essential thrombocythemia in, **1220**

focal pathology of, **1213**

follicular hyperplasia of, **1213**

follicular lymphoma in, **363**, **364f**

gross examination of, **1211–1213**, **1212t**

in hairy cell leukemia, **330**, **331f**

hamartoma of, **1222t**, **1225**, **1225f**

hemangioma of, **1221–1222**, **1222t**

hemophagocytic syndromes in, **1221**, **1221f**, **1221b**

hepatosplenic T-cell lymphoma in, **676**, **677f**

Hodgkin lymphoma in, **1214–1215**, **1215f**

inflammatory pseudotumor-like dendritic cell sarcoma of, **1226**

juvenile myelomonocytic leukemia in, **1219–1220**, **1220f**

littoral cell angioma of, **1222–1223**, **1222t**, **1223f**

lymphangioma of, **1223–1224**

lymphoid hyperplasia of, **1213–1214**, **1213f**

lymphoma in

primary, **1215–1216**

secondary, **1216**

lymphoplasmacytic lymphoma and Waldenström macroglobulinemia in, **315**, **317f**

MALT lymphoma in, **393**, **397f**

mantle cell lymphoma in, **432**

mastocytosis in, **984–985**, **984f**

mesenchymal tumors and non-neoplastic disorders that mimic neoplasms in, **1221–1225**

myeloid neoplasms in, **1217–1220**, **1218f**

myeloproliferative neoplasms in, **1218–1220**

non-Hodgkin lymphomas in, **1215–1216**

normal, **1211**, **1211t**, **1212f**

normal architecture and neoplastic and non-neoplastic lesions of, **1210–1227.e5**

pearls and pitfalls in, **1227**, **1227b**

open circulation of, **1211**

other tumors of, **1226**

peliosis of, **1224–1225**

polycythemia vera in, **1218–1219**

precursor lymphoid neoplasms in, **1216**

primary B-cell lymphoid neoplasms presenting with prominent splenomegaly, **1217**

primary myelofibrosis in, **1219–1220**, **1219f**, **1219t**

proliferations of the monocyte-macrophage system in, **1221**

reactive pseudotumoral lesions of, **1225–1226**

red pulp of, **1211**

rupture of, **1213**

sarcoid granuloma in, **1214**

sclerosing angiomatoid nodular transformation of, **1222t**, **1224**, **1224f**

signet ring carcinoma metastatic to, **1227f**

splenic marginal zone lymphoma in, **339**, **340f**

storage diseases and, **1226–1227**

in systemic EBV-positive T-cell lymphoma of childhood, **621**, **622f–623f**

systemic mastocytosis in, **1220**, **1220f**

T-cell and NK-cell neoplasms in, **1217**

T-cell/histiocyte-rich large B-cell lymphoma in, **469**

T-cell lymphoid neoplasms presenting with prominent splenomegaly, **1217**

T-cell prolymphocytic leukemia in, **655**

vascular and other nonhematopoietic primary tumors of, **1222t**

white pulp of, **1211**

Splenectomy, for T-cell large granular lymphocytic leukemia, **653**

Splenic cysts, **1226**

Splenic diffuse red pulp small B-cell lymphoma (SDRPSBL), **348–350**, **349f–350f**, **1212t**

hairy cell leukemia and, **335**, **336t**

Splenic infiltrates, peripheral T-cell lymphoma in, **693f**, **695**

Splenic marginal zone lymphoma (SMZL), **338–351.e3**, **79**, **1212t**

antigen receptor genes in, **344–345**

in T-cell prolymphocytic leukemia, **659f**, **660**

TdT, *See* **Terminal deoxynucleotidyl transferase**

TEMPI syndrome, **541–542**

clinical and laboratory features of, **541**

definition of, **541**

differential diagnosis of, **542**

etiology, epidemiology, and genetics of, **541**

immunophenotypic features of, **542**

morphology of, **541–542**

POEMS syndrome and, **542**

treatment and prognosis of, **542**

Terminal deoxynucleotidyl transferase (TdT)

in B-cell lymphoblastic leukemia/lymphoma, **809**
in blastic plasmacytoid dendritic cell neoplasm, **1025**
in T-cell lymphoblastic leukemia/lymphoma, **816**
Tertiary lymphoid organs, **147**
Testis, lymphoma of, **1251–1252**
TET2 mutations, **95**
α-thalassemia, **208t**, **210–211**, **211f**
β-thalassemia, **208t**, **209–210**, **210f**
δβ-thalassemia, **211**
α-thalassemia trait, **210–211**, **211f**
Thalassemias, **208–211**, **208t**, **210f–211f**, **210t**
hydrops fetalis and, **210–211**, **211f**
Therapy-related myeloid neoplasms, **913–914**
Thrombocythemia, essential, **933–938**
versus atypical chronic myeloid leukemia, **968**
clinical course of, **934–935**, **935b**
clinical features of, **933**
definition of, **933**
diagnosis of, **934b**
differential diagnosis of, **936–938**, **936b**
other myeloid neoplasms associated with, **936–938**, **936t**, **937f**

reactive thrombocytosis in, **936**
epidemiology of, **933**
in extramedullary tissues, **934**
genetics of, **934**
cytogenetics of, **934**
mutations in, **934**
morphology of, **933–934**
in spleen, **1220**
Thrombocytopenia, **842t**
acquired, with normal-to-increased megakaryocytes, **240t**
constitutional, **239t**, **244–245**
with normal-to-increased megakaryocytes, **241t**
with decreased or absent bone marrow megakaryocytes, **239t**
evaluation of, **237–245**, **242f**, **249b**
heparin-induced, **239–242**
in hepatosplenic T-cell lymphoma, **676**
immune
primary, **238–239**
secondary, **239**
immune-mediated, **238–239**
infection-associated, **242**, **242f**

mantle cell lymphoma and, **428**

from microangiopathic processes, **243f**

neonatal, **243**

secondary to microangiopathic processes, **243**

splenic sequestration in, **244**

Thrombocytopenic purpura, **243f**

immune, **238**

thrombotic, **243f**

Thrombocytosis, **842t**, **936**

causes of, **936b**

in chronic inflammatory conditions, **261**

myelodysplastic/myeloproliferative neoplasm with, **968–970**, **968b**

characteristics of, **968**

cytogenetics and genetics of, **970**

differential diagnosis of, **970**

immunophenotype in, **970**

morphology of, **968–970**

prognosis and prognostic factors of, **970**

Thrombopoietin, recombinant, bone marrow changes after, **1161**

Thrombotic thrombocytopenic purpura, **243f**

Thymic carcinoid, primary mediastinal (thymic) large B-cell lymphoma and, **476t**

Thymic carcinoma, primary mediastinal (thymic) large B-cell lymphoma and, **476**, **476t**

Thymic epithelial space, **136**

Thymic medulla, **137**

Thymocytes

cortical, **136–137**, **154–155**

medullary, **136–137**

Thymoma, **24**

pure red cell aplasia and, **216–217**

Thymus

classic Hodgkin lymphoma in, **566**, **573**

histology in, **1087f**

Langerhans cell histiocytosis in, **1058**

lymphoid tissues in, **136–138**, **137f**

lymphoma of, **1242**, **1243f**

in SCID and CID, **1087**

Thyroid, lymphoma of, **1239–1240**, **1240f**

TIA-1

in anaplastic large cell lymphoma, **719**, **723f**

in peripheral T-cell lymphoma, not otherwise specified, **693**

t(14;18)(q32;q21)*IGH*::*BCL2* translocation, **130**

Tingible body macrophages

in B-cell lymphoblastic leukemia/lymphoblastic lymphoma, **808–809**

in dark zone, **139**

TNF-α antagonists, lymphoproliferative disorder associated with, **1120**

TNF-alpha, in EBV-associated hemophagocytic lymphohistiocytosis, **611–612**

Tonsil, Burkitt lymphoma in, **1236f**

Topoisomerase II alpha enzyme (TOP2A), in lymphocyte-predominant cells, **548t–549t**, **551**

Touch imprint, of lymph node biopsy specimen, **5**, **7f**

Toxoplasma gondii pseudocysts, bone marrow findings in, **255**

Toxoplasmic lymphadenitis, **175–176**, **177f**

TP53 mutations, **97**

in diffuse large B-cell lymphoma, **454–455**, **463**

in extranasal NK/T-cell lymphoma, **633**

in mantle cell lymphoma, **438**

in myelodysplastic/myeloproliferative neoplasms, **962**

TP73L, in lymphocyte-predominant cells, **548t–549t**

TPM3-ALK protein, **721–724**

TRAF1, in lymphocyte-predominant cells, **548t–549t**

Transcription factors

- myelodysplastic syndromes and, **846–847**, **848t**
- regulators and, in nodular lymphocyte predominant B-cell lymphoma, **548t–549t**, **550**
- in T-cell lymphoblastic leukemia/lymphoma, **818**

Transcriptome sequencing, **74–75**

Transferrin saturation, in iron deficiency, **207–208**

Transient abnormal myelopoiesis, **910**, **911f**

Translocations

- in normal individuals, **106–107**, **106t**
- reciprocal, **110**
- unbalanced, **110**

Transplantation, hematopoietic stem cell

- bone marrow evaluation after, **1158**, **1160b**
- for T-cell prolymphocytic leukemia, **661**

Triploid, **109**

Trisomy, **110**

Trisomy 12, in chronic lymphocytic leukemia/small lymphocytic lymphoma, **291–292**, **296f**

Tropheryma whipplei, bone marrow findings in, **253**

Tropical spastic paralysis (TSP), **663–664**

Tryptase-positive compact round cell infiltrate of the bone marrow (TROCI-bm), **987–989**

t(8;14)(q24;q32) translocation, **128–129**

Tuberculosis, granulomatous lymphadenitis in, **172**

Tumor, enrichment of, **65–66**

Tumor lysis syndrome, in Burkitt lymphoma, **485–486**

Tumor necrosis factor-α, in systemic Epstein-Barr virus-positive T-cell lymphoma of childhood, **621**

Tumor suppressors

in lymphocyte-predominant cells, **548t–549t**

myelodysplastic syndromes and, **846–847**, **848t**

Type I interferons, **1029**

Tyramide-based signal amplification, in immunohistochemistry, **33**

Tyrosine kinase, myeloproliferative neoplasms, **118–120**

Tyrosine kinase gene fusions, **102**

Tyrosine kinase inhibitor therapy, for chronic myeloid leukemia, **926–928**

U

Ulcerative jejunitis, in refractory celiac disease, **740f**, **744**

Ureter, lymphoma of, **1250**

Urethra, lymphoma of, **1250–1251**

Urinary bladder, lymphoma of, **1250–1251**

Urine protein electrophoresis, in multiple myeloma, **510**, **511f**

Uterine leiomyomas, with lymphoid infiltration, **1255**

Uterine lymphoma, **1253–1254**, **1254f–1255f**

V

VAF, *See* **Low-variant allele frequency**

Vaginal lymphoma, **1254–1255**

Variant allele frequency (VAF), **869**

Vascular invasion, in follicular lymphoma, **356**

Vascular transformation

- of lymph node sinuses and lymphatic proliferations, **1203**, **1203f**
- of sinuses, **169–170**, **170f**

Vascular tumors

- of lymph nodes, **1205–1206**, **1206f–1207f**
- of spleen, **1222t**

Vβ repertoire analysis, in T-cell neoplasms, **55–56**

VEXAS syndrome

bone marrow failure syndrome in, **248**, **248f**

myelodysplastic syndrome *versus*, **863**

Vimentin, in lymphocyte-predominant cells, **548t–549t**, **551**

Viral infections

of bone marrow, **255–257**, **256f–258f**

chronic, myelodysplastic syndrome *versus*, **861–862**

Vitamin B_{12} deficiency, **225**, **226t**

Vitiligo, mycosis fungoides and, **766–767**

Vitreoretinal lymphoma, **1232–1233**

Vulvar lymphoma, **1254–1255**

W

Waldenström macroglobulinemia

bone marrow involvement in, **1134–1135**, **1137f**

lymphoplasmacytic lymphoma and, **310–326.e6**

in bone marrow, **311–315**, **313f–314f**

in cerebrospinal fluid, **315**, **319f**

clinical course of, **322–323**

clinical features of, **311**

cytogenetic abnormalities in, **321–322**

definition of, **310**

diagnostic features of, **312b**
differential diagnosis of, **323–325**
epidemiology of, **311**
IgM-secreting disorders in, **325**
immunophenotype of, **315–321**
in lymph nodes, **315**, **318f**
molecular genetic findings of, **321–322**
morphology of, **311–315**
MYD88 L265P mutation in, **320f**, **321**
neoplastic conditions in, **323–324**, **324b**
pathogenesis of, **322**
pearls and pitfalls in, **326**, **326b**
peripheral blood findings in, **311**, **312f**
postulated normal counterpart of, **322**
prognosis of, **322–323**
somatic mutations in, **321**
in spleen, **315**, **317f**
synonyms and related terms of, **310–311**
treatment of, **322–323**
Waldeyer's ring, lymphoma of, **1235–1236**, **1235f–1236f**
Warthin-Starry stain, for lymph node biopsy specimen, **11–12**

Warts, hypogammaglobulinemia, infections, and, myelokathexis (WHIM), **1102**, **1102f**

WAS gene, in Wiskott-Aldrich syndrome, **1100–1101**

Wegener's granulomatosis

versus extranasal NK/T-cell lymphoma, **634**, **635t**

versus lymphomatoid granulomatosis, **598b**

WHIM syndrome, neutropenia in, **234t**, **236**

Whipple disease, histiocytic expansion in, **169**, **170f**

White pulp, **144**

WHO classification

of acute myeloid leukemia, **890**, **890b**

of lymphoid neoplasms, **269**

of mastocytosis, **975**, **976b**

of myelodysplastic/myeloproliferative neoplasms, **953–954**, **954b**

of myelodysplastic syndromes, **852–857**, **853t**

Whole chromosome painting probes (WCP), **112**

Whole exome sequencing, **74–75**, **1085**

Whole genome sequencing (WGS), **74**, **1085**

Whole slide imaging, for lymph node biopsy specimen, **11**

Wiskott-Aldrich syndrome, **1100–1102**

Woringer-Kolopp disease, **770f**

Wright-Giemsa stain
for fine-needle aspiration, **16**
for lymph node biopsy specimen, **7–8**

X

X-linked agammaglobulinemia, **1096–1097**
X-linked inhibitor of apoptosis protein (XIAP), **1096**
X-linked lymphoproliferative disease, **1035**, **1096–1097**
X-linked sideroblastic anemia, **214–215**

Z

ZAP-70, in chronic lymphocytic leukemia/small lymphocytic lymphoma, **288–289**, **294f**
ZBTB16::*RARA,* in acute promyelocytic leukemia, **893–894**, **894f**
Zinc formalin, for lymph node biopsy specimen, **9t**
Zinc toxicity, myelodysplastic syndrome *versus*, **861**
